Periodic noise is the result of the variation of fluorescent lighting due to the method of driving the lamp using the ballast. This generates an extraneous periodic signal with a fundamental frequency of 44 kHz with significant harmonics to several megahertz. Mitigating the effect of periodic noise can be done using highpass filtering in combination with baseline restoration [6], or by careful selection of the modulation type, as discussed in Section 3.1.

2.4. Safety

There are two safety concerns when dealing with infrared communication systems. Eye safety is a concern because of a combination of two effects. First, the cornea is transparent from the near violet to the near IR. Hence, the retina is sensitive to damage from light sources transmitting in these bands. Secondly, however, the near IR is outside the visible range of light, and so the eye does not protect itself from damage by closing the iris or closing the eyelid. Eye safety can be ensured by restricting the transmit beam strength according to IEC or ANSI standards [7,8].

Skin safety is also a possible concern. Possible short-term effects such as heating of the skin are accounted for by eye safety regulations (since the eye requires lower power levels than does the skin). Long-term exposure to IR light is not a concern, as the ambient light sources are constantly submitting our bodies to much higher radiation levels than these communication systems do.

3. COMMUNICATIONS DESIGN

Equally important for achieving the design goals of wireless infrared systems are communications issues. In particular, the modulation signal format together with appropriate error control coding is critical to achieving power efficiency. Channel characterization is also important for understanding performance limits.

3.1. Modulation Techniques

To understand modulation in IM/DD systems, we must look again at the channel model

$$Y(t) = X(t) \otimes c(t) + N(t)$$

and consider its particular characteristics. First, since we are using intensity modulation, the channel input $X(t)$ is optical intensity and we have the constraint $X(t) \geq 0$. The

average transmitted optical power P_T is the time average of $X(t)$. Our goal is to minimize the transmitted power required to attain a certain probability of bit error P_e , also known as a bit error rate (BER).

It is useful to define the signal-to-noise ratio (SNR) as

$$\text{SNR} = \frac{R^2 H^2(0) P_t^2}{R_b N_0}$$

where $H(0)$ is the DC gain of the channel, i.e., it is the Fourier transform of $h(t)$ evaluated at zero frequency, so

$$H(0) = \int_{-\infty}^{\infty} h(t) dt.$$

The transmitted signal can be represented as

$$X(t) = \sum_{n=-\infty}^{\infty} s_{a_n}(t - nT_s).$$

The sequence $\{a_n\}$ represents the digital information being transmitted, where a_n is one of L possible data symbols from 0 to $L - 1$. The function $s_i(t)$ represents one of L pulseshapes with duration T_s , the symbol time. The data rate (or bit rate) R_b , bit time T , symbol rate R_s , and symbol time T_s are related as follows: $R_b = 1/T$, $R_s = 1/T_s$, and $T_s = \log_2(L)T$.

There are three commonly used types of modulation schemes: on/off keying (OOK) with non-return-to-zero (NRZ) pulses, OOK with return-to-zero (RZ) pulses of normalized width δ (RZ- δ), and pulse position modulation with L pulses (L -PPM). OOK and RZ- δ are simpler to implement at both the transmitter and receiver than L -PPM. The pulse shapes for these modulation techniques are shown in Fig. 3. Representative examples of the resulting transmitted signal $X(t)$ for a short data sequence are shown in Fig. 4.

We compare modulation schemes in Table 1 by looking at measures of *power efficiency* and *bandwidth efficiency*. Bandwidth efficiency is measured by dividing the zero-crossing (ZC) bandwidth by the data rate. Bandwidth-efficient schemes have several advantages—the receiver and transmitter electronics are cheaper, and the modulation scheme is less likely to be affected by multipath distortion. Power efficiency is measured by comparing the required transmit power to achieve a target probability of error P_e for different modulation techniques. Both RZ- δ and PPM are more power-efficient than OOK, but at the cost of reduced bandwidth efficiency. However, for a given bandwidth efficiency, PPM is more power-efficient than RZ- δ , and so PPM is most commonly used. OOK is most useful at very high data rates, say 100 Mbps (megabits per second) or greater. Then, the effect of multipath distortion is the most significant effect and bandwidth efficiency becomes of paramount importance [9].

3.2. Error Control Coding

Error control coding is an important technique for improving the quality of any digital communication system. We concentrate here on forward error correction channel

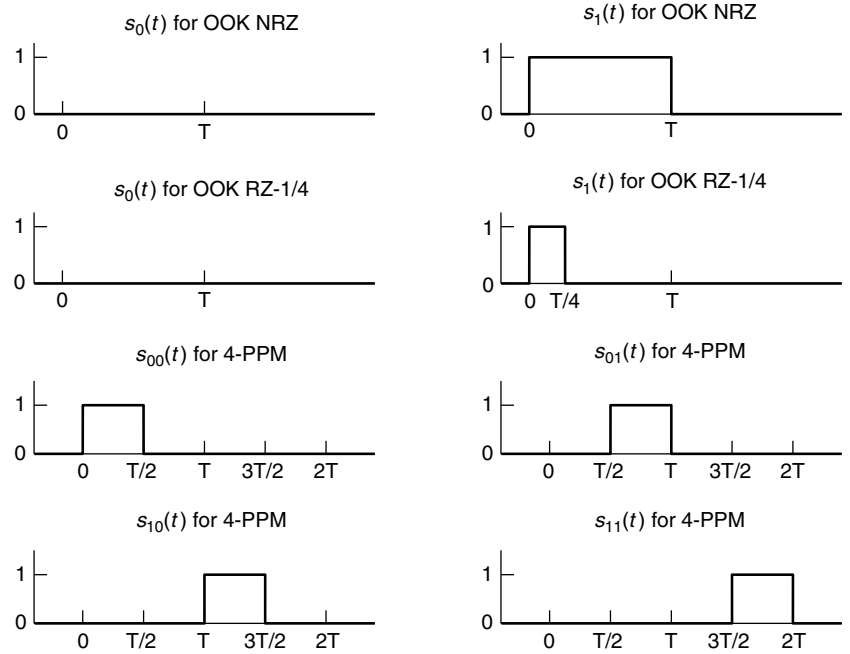

Figure 3. The pulse shapes for OOK, RZ-0.25, and 4-PPM.

Figure 4. The transmitted signal for the sequence 010011 for OOK, RZ-0.25, and 4-PPM.

coding, as this specifically relates to wireless infrared communications; source coding and ARQ (automatic repeat request) coding are not considered here.

Trellis-coded PPM has been found to be an effective scheme for multipath infrared channels [10,11]. The key technique is to recognize that although on a distortion-free channel, all symbols are orthogonal and equidistant

in signal space, this is not true on a distorting channel. Hence, trellis coding using set partitioning designed to separate the pulse positions of neighboring symbols is an effective coding method. Coding gains of 5.0 dB electrical have been reported for rate $\frac{2}{3}$ -coded 8-PPM over uncoded 16-PPM, which has the same bandwidth [11].

3.3. Channel Impulse Response Characterization

Impulse response characterization refers to the problem of understanding how the impulse response $c(t)$ in Eq. (1) depends on the location, size, and orientation of the receiver and transmitter. There are basically three classes of techniques for accomplishing this: measurement, simulation, and modeling. Channel measurements have been described in several studies [2,9,12], and these form the fundamental basis for understanding the channel properties. A particular study might generate a collection of hundreds or thousands of example impulse responses $c_i(t)$ for configuration i . The collection of measured impulse responses $c_i(t)$ can then be studied by looking at scatterplots of path loss versus distance, scatterplots of delay spread versus distance, the effect of transmitter and receiver orientations, robustness to shadowing, and so on.

Simulation methods have been used to allow direct calculation of a particular impulse response based on a site-specific characterization of the propagation

Table 1. Comparison of Modulation Schemes on Ideal Channels

Modulation Type	P_e	ZC Bandwidth
On/off keying (OOK)	$Q(\text{SNR}^{1/2})$	R_b
OOK RZ- δ	$Q(\delta^{-1/2} \text{SNR}^{1/2})$	$\frac{1}{\delta} R_b$
L-PPM	$Q((0.5L * \log_2(L))^{1/2} \text{SNR}^{1/2})$	$\frac{L}{\log_2 L} R_b$

environment [13,14]. The transmitter, the receiver, and the reflecting surfaces are described and used to generate an impulse response. The basic assumption is that most interior surfaces reflect light diffusely in a Lambertian pattern, that is, all incident light, regardless of incident angle, is reflected in all directions with an intensity proportional to the cosine of the angle of the reflection with the surface normal. The difficulty with existing methods is that accurate modeling requires extensive computation.

A third technique attempts to extract knowledge gained from experimental and simulation-based channel estimations into a simple-to-use model. In Ref. 15, for example, a model using two parameters (one for path loss, one for delay spread) is used to provide a general characterization of all diffuse IR channels. Methods for relating the parameters of the model to particular room characteristics are given, so that system designers can quickly estimate the channel characteristics in a wide range of situations.

4. STANDARDS AND SYSTEMS

We examine the details of the two dominant wireless infrared technologies, IRDA and IEEE 802.11, and other commercial applications.

4.1. Infrared Data Association Standards (IRDA)

The Infrared Data Association [16], an association of about 100 member companies, has standardized low-cost optical data links. The IRDA link transceivers or “ports,” appear on many portable devices, including notebook computers, personal digital assistants, and also computer peripherals such as printers.

The series of IRDA transmission standards are described in Table 2. The current version of the physical-layer standards is IrPHY 1.3. Data rates ranging from 2.4 kbps to 4 Mbps are supported. The link speed is negotiated by starting at 9.6 kbps.

Most of the transmission standards are for short-range, directed links with an operating range from 0 to 1 m. The transmitter half-angle must be between 15° and 30°, and the receiver field-of-view half-angle must be at least 15°. The transmitter must have a peak-power wavelength between 850 and 900 nm.

4.2. IEEE 802.11 and Wireless LANs

The IEEE has published a set of standards for wireless LANs, IEEE 802.11 [17]. The IEEE 802.11 standard is designed to fit into the structure of the suite of IEEE 802 LAN standards. Hence, it determines the physical layer (PHY) and medium-access control layer (MAC) leaving the logical link control (LLC) IEEE 802.2. The MAC layer uses a form of carrier-sense multiple access with collision avoidance (CSMA/CA).

The original standard supports both radio and optical physical layers with a maximum data rate of 2 Mbps. The IEEE 802.11b standard adds a 2.4-GHz radio physical layer at up to 11 Mbps and the IEEE 802.11a standard adds a 5.4-GHz radio physical layer at up to 54 Mbps.

The two supported data rates for infrared IEEE 802.11 LANs are 1 and 2 Mbps. Both systems use PPM but share a common chip rate of 4 Mc/s, as explained below. Each frame begins with a preamble encoded using 4 Mbps OOK. In the preamble, a 3-bit field indicates the transmission type, either 1 or 2 Mbps (the six other types are reserved for future use). The data are then transmitted at 1 Mbps using 16-PPM or 2 Mbps using 4-PPM. 16-PPM carries $\log_2(16)/16 = \frac{1}{4}$ bits/chip, and 4-PPM carries $\log_2(4)/4 = \frac{1}{2}$ bit/chip, resulting in the same chip time for both types.

The transmitter must have a peak-power wavelength between 850 and 950 nm. The required transmitter and receiver characteristics are intended to allow for reliable operation at link lengths up to 10 m.

4.3. Building-to-Building Systems

Long-range (>10 m) infrared links must be directed LoS systems in order to ensure a reasonable path loss. The emerging products for long-range links are typically designed to be placed on rooftops [18,19], as this provides the best chance for establishing line-of-sight paths from one location to another in an urban environment. These high-data-rate connections can then be used for enterprise network access or metropolitan- or campus-area networks.

Several design issues are specific to these systems that are unique to these long-range systems [3]: (1) *atmospheric path loss*, which is a combination of clean-air absorption from the air and absorption and scattering from particles in the air, such as rain, fog, and pollutants;

Table 2. IRDA Data Transmission Standards

Version	Link Type	Link Range (m)	Data Rate	Modulation
1.3	Point-to-point	1	2.4–115.2 kbps	RZ- $\frac{3}{16}$
1.3	Point-to-point	1	576 kbps	RZ- $\frac{1}{4}$
			1152 kbps	RZ- $\frac{1}{4}$
1.3	Point-to-point	1	4 Mbps	4-PPM
VFIR ^a /1.4	Point-to-point	1	16 Mbps	OOK
AIR ^b /proposed	Network	4	4 Mbps	—
		8	250 kbps	—

^aVFIR = Very Fast Infrared.

^bAIR = Advanced Infrared.

(2) *scintillation*, which is caused by temperature variations along the LoS path, causing rapid fluctuations in the channel quality; and (3) *building sway*, which can affect alignment and result in signal loss unless the transceivers are mechanically isolated or active alignment compensation is used.

4.4. Other Applications

Wireless infrared communication has found several markets in and around the home, car, and office that fall outside the traditional telecommunications markets of voice and data networking. These can be classified as either wireless input devices or wireless control devices, depending on one's perspective. Examples include wireless computer mice and keyboards, remote controls for entertainment equipment, wireless videogame controllers, and wireless door keys for home or vehicle access. All such devices use infrared communication systems because of the attractive combination of low cost, reliability, and light weight in a transmitter/receiver pair that achieves the required range, data rate, and data integrity required.

5. TECHNOLOGY OUTLOOK

In this section, we discuss how competition from radio and developments in research will impact the future uses of wireless infrared communication systems.

5.1. Comparison to Radio

Wireless infrared communication systems enjoy significant advantages over radio systems in certain environments. First, there is an abundance of unregulated optical spectrum available. This advantage is shrinking somewhat as the spectrum available for licensed and unlicensed radio systems increases with the modernization of spectrum allocation policies.

Radio systems must make great efforts to overcome or avoid the effects of multipath fading, typically through the use of diversity. Infrared systems do not suffer from time-varying fades because of the inherent diversity in the receiver, thus simplifying design and increasing operational reliability.

Infrared systems provide a natural resistance to eavesdropping, as the signals are confined within the walls of the room. This also reduces the potential for neighboring wireless communication systems to interfere with each other, which is a significant issue for radio-based communication systems.

In-band interference is a significant problem for both types of systems. A variety of electronic and electrical equipment radiates in transmission bands of current radio systems; microwave ovens are a good example. For infrared systems, ambient light, either human-made (synthetic) or natural, is a dominant source of noise.

The primary limiting factor of infrared systems is their limited range, particularly when no good optical path can be made available. For example, wireless communication between conventional rooms with opaque walls and doors

cannot be accomplished; one must resort to using either a radio-based or a wireline network to bypass the obstruction.

5.2. Research Challenges

Various techniques have been considered to improve on the performance of wireless infrared communication systems.

At the transmitter, the radiation pattern can be optimized to improve performance characteristics such as range. Some optical techniques for achieving this are diffusing screens, multiple-beam transmitters, and computer-generated holographic images.

At the receiver, performance is ultimately determined by signal collection (limited by the size of the photodetector) and by ambient noise filtering. Optical interference filters can be used to reduce the impact of background noise; the primary difficulty is in achieving a wide field of view. This can be done using nonplanar filters or multiple narrow-FoV receiving elements.

Some recent developments and research programs are described in Ref. 20, and an on-line resource guide is maintained in Ref. 21.

6. CONCLUSIONS

Wireless infrared communication systems provide a useful complement to radio-based systems, particularly for systems requiring low cost, lightweight, moderate data rates, and only requiring short ranges. When LoS paths can be ensured, range can be dramatically improved to provide longer links.

Short-range wireless networks are poised for tremendous market growth in the near future, and wireless infrared communications systems will compete in a number of arenas. Infrared systems have already proved their effectiveness for short-range temporary communications and in high-data-rate, longer-range point-to-point systems. It remains an open question whether infrared will successfully compete in the market for general-purpose indoor wireless access.

BIOGRAPHY

Jeffrey B. Carruthers received his B.Eng. degree in computer systems engineering from Carleton University, Ottawa, Canada, in 1990, and M.S. and Ph.D. degrees in electrical engineering from the University of California, Berkeley, California, in 1993 and 1997, respectively. Since 1997, he has been an assistant professor in the Department of Electrical and Computer Engineering at Boston University, Boston, Massachusetts. Previously, he was with SONET Development Group of Bell-Northern Research, Ottawa, Canada, from 1990 to 1991. From 1992 to 1997 he was a research assistant at the University of California, Berkeley. Dr. Carruthers was an NSERC 1967 Postgraduate Scholar, and he received the National Science Foundation CAREER Award in 1999. His research interests include wireless infrared communications, wireless networking, and digital

communications. He is a member of the IEEE and the IEEE Communications Society.

WIRELESS IP TELEPHONY

DAVID R. FAMOLARI
Telecordia Technologies
Morristown, New Jersey

1. INTRODUCTION

No two innovations have done more in the 1990s to advance communications than the wireless cellular telephone network and the Internet. Wireless cellular telephony extended access to the Public Switched Telephone Network (PSTN), the conventional landline telephone system, to users with small handheld radio terminals. These users could then establish and maintain voice calls anywhere within radio coverage, which for practical purposes in the United States is nationwide. This ushered in an era of *mobile* communications that disassociated a telephone user with a geographic location. No longer did dialing a particular number ensure that a caller would find (or not find) the intended recipient “at home,” “at work,” or elsewhere; with wireless telephony they could in fact be anywhere. And so could the caller. The desire to be mobile, coupled with falling subscription charges and rising voice quality, motivate an increasing number of customers to flock to the cellular telephone network. The reliability and quality of wireless phone service has even prompted some to forego landline service all together. Simply put, wireless telephony has made good on the promise of anywhere/anytime voice communications.

Based on the unifying, packet switching Internet Protocol (IP) [1], the Internet has had no less a dramatic impact on how society communicates. Its advent has interconnected devices over vast distances at limited costs and made possible rich multimedia content exchanges, most notably with the emergence of the World Wide Web (WWW). The open and standard protocols of the Internet allow equipment vendors to easily produce infrastructure products that interoperate with other vendor’s products, increasing competition and fostering economies of scale. This has led to the pronounced deployment of Internet architecture throughout the world and, consequently, extended the reach of the Internet on a global scale. Because of its reach and its ability to support a variety of services, the Internet has evolved from a loose interconnection of computers employed by researchers to exchange files into a global network infrastructure that is an essential underpinning to commercial, governmental, and private communication.

Both the Internet and wireless telephony have created unprecedented operating freedoms and are forcing paradigm shifts in business and social communication practices. Their impact, however, has emerged from opposite design philosophies. The wireless telephone network provides ubiquitous access to speech applications; the Internet, on the other hand, delivers a wide variety of application types to fixed locations. The freedom and mobility offered by wireless networks provides a perfect compliment to the economies of scale and flexibility offered by the IP-based Internet.

Now, at the beginning of the twenty-first century, the two most defining communications breakthroughs of the late twentieth century are starting to merge. As IP becomes an important driver of both core and access networks, it must support wireless voice at comparable levels of spectrum efficiency and voice quality as cellular telephony. Similarly, wireless network practices must be modified to accommodate IP-based packet protocols. It is our aim here to describe the design challenges and technical hurdles facing successful deployment of wireless IP telephony.

2. BACKGROUND AND BASIC CONCEPTS

The design goals of the current breed of wireless telephony standards, commonly referred to as *second-generation* (2G)¹ standards, were to carry digital voice conversations to and from the PSTN with packet data networking only as an afterthought. As a consequence, current cellular systems have only limited packet data capabilities, usually to exchange brief text messages such as the Short Message Service (SMS). However new breeds of cellular communications systems are promising advanced features for packet data networking, along with faster transmission speeds and higher capacity. These new communications systems are widely referred to as *third-generation* (3G) systems. It is in 3G systems that the first steps are being taken towards integrating IP transport with wide-area wireless networks.

The new breed of 3G systems were initiated by the International Telecommunications Union (ITU), a United Nations governing body, under a directive called "International Mobile Telecommunications for the year 2000" (IMT-2000). IMT-2000 is a family of guideline specifications and recommendations serving as an umbrella standard to harmonize the evolution of the disparate 2G radio technologies currently in place; most notably the CDMA-based IS95 systems in the United States and the GSM systems in Europe and elsewhere. Regionalized activities within the IMT-2000 family emerged based on these two technologies. These include the Third Generation Partnership Project (3GPP), centered on evolving the GSM standard under the name Universal Mobile Telecommunications Service (UMTS) [2], and the Third Generation Partnership Project 2 (3GPP2), focused on evolving the IS95 standard, referred to as "cdma2000" [3].² Both groups are actively mapping out architectures and protocol references to support high-rate packet data services that will be used to carry IP telephony over their respective networks.

The challenges that these groups will face are to accommodate three fundamental issues in successful

delivery of wireless voice. These issues are service quality of the perceived voice output stream, efficient use of the band-limited medium, and mobility of wireless users.

1. *Service Quality.* Wireless telephone systems have been efficiently designed to carry one type of application: voice, a time-sensitive, error-tolerant communication service. Its perceived quality degrades more rapidly when the delay characteristics of the underlying delivery change than as the error characteristics change. The destination of each call is usually a human being who can compensate for imperfections in the received signal. This is akin to deriving the proper meaning of a sentence when a word or two is mispronounced. When sounds arrive with noticeable variation in their inter-arrival times (called *jitter*), or when there are long lapses in the conversation (*delay*), conversation can become tedious. Circuit switched principles, at the core of wireless telephone systems, are well suited for voice since they offer timely and regular access to the transport medium. The Internet, on the other hand, thrives on the principles of packet switching. Consequently IP packets often take different routes through the network and can arrive out of sequence with variable delays. Therefore the basic IP protocols are not well suited to deliver time-sensitive applications such as voice.

2. *Efficiency.* Wireless telephony contends with limited spectrum and an unpredictable, time-varying physical channel that is subject to path loss, fading, and multiple-access interference. In order to support high capacity and revenue, service providers must make best utilization of their given spectrum. To this end, cellular telephony employs techniques that make best use of scarce, unreliable resources to deliver near-toll-quality voice. These techniques include employing low-bit-rate voice codecs to compress speech and reducing frame sizes to make voice packets less vulnerable to rapid fluctuations in the channel. The protocols and architecture of the Internet give prominence to end-to-end principles over centralized approaches. While offering flexibility, this demands that each packet contain a greater degree of control information than circuit-switched packets. The additional control information is embedded in the detailed protocol headers that are included in each IP data packet. Consequently, squeezing these heavyweight protocol headers into the relatively small packet sizes of the wireless channel gives rise to a number of performance problems related to efficiency.

3. *Mobility.* A fundamental design concept of wireless telephony is to allow users to seamlessly change their point of attachment to the network at any time. This must occur without explicit reconfiguration or significant performance loss. IP routing, however, associates an IP address with a fixed attachment to a router. When this association is no longer valid, as is the case when wireless users move, standard IP routing procedures are unable to deliver packets to and from the mobile terminal. Furthermore, re-establishing a valid association under the standard IP procedure may require manual intervention and explicit reconfiguration that will terminate any ongoing communications. Therefore these routing protocols require

¹ Second-generation systems represented a significant leap from the first generation Analog Mobile Phone System (AMPS), including the use of digital modulation techniques, enhanced security features, better spectral efficiency and longer mobile terminal battery life.

² For more detail on 3G wireless standards, the reader is referred to Ref. 4.

extensions and additional control architectures to transfer associations in midsession. In other words, mobility solutions for IP will need to offer seamless transfers in order to support wireless voice effectively.

In the remainder of this chapter we focus on each of these three principles and discuss modifications to the IP protocols and architecture to successfully offer IP telephony services.

3. SERVICE QUALITY FOR WIRELESS IP TELEPHONY

Service quality can be characterized by three parameters; packet loss, delay, and delay variability. In the wired network, heavy traffic at ingress points can overload IP routers, causing packets to be dropped. Even in the absence of heavy traffic, the detrimental effects of the wireless channel can corrupt voice packets so that they cannot be recovered at the receiver and are considered lost. Packet loss is therefore a considerable problem on wireless links. One-way delay is the time from when a voice packet enters the encoder at the source terminal to when it exits the decoder at the destination terminal. As mentioned earlier, the variability in packet arrival times is referred to as jitter. These three parameters are interdependent and all contribute to the overall service quality. In wireless networks where packet loss can be high, delay and jitter will increase correspondingly. Human perceptions can accommodate reasonable delays, but service quality becomes degraded when those delays have a high variation from packet to packet.

Wireless IP telephony service quality is dependent upon two issues: the service quality that voice receives over the air interface and the service quality that it receives while traversing the wired backbone network of the service provider. *Wired IP service quality* management has been a topic of much research. Many efforts have been geared toward supporting classes of service above and beyond the best-effort service of the typical Internet. These technologies attempt to provide more reliable delay and jitter performance by classifying traffic and giving priority treatment to certain traffic classes. We focus here on the service quality aspects particular to *wireless* transmission and refer the reader to Refs. 5–7 for more detailed information on wired service quality measures.

3.1. Wireless Service Quality

3.1.1. Link-Layer Solutions. Information transfer over wireless links is subject to impairments and environmental constraints that landline communications are free from. Factors affecting the wireless channel include interference, shadowing, path loss, and fading. These affects can have dramatic negative impacts on the signal-to-interference ratio (SIR). Lower SIR levels lead to increases in the frame error rates (FERs). Higher FER, in turn, increases packet loss. Furthermore, these wireless channel effects vary over small distances making signal quality very sensitive to terminal mobility. Simply increasing the bit rate cannot overcome the impediments of the wireless channel. Though all 3G systems will offer much higher

available bandwidths for packet data [supporting rates of 144 kbps (kilobits per second) at high mobility rates, 384 kbps at pedestrian mobility rates, and 2 Mbps for indoor systems], voice service quality is still primarily dependent on achieving timely delivery of good-quality voice packets.

In order to improve the quality of the voice packets, wireless networks have focused on making voice packets more robust to transmission errors. In addition to physical-layer solutions that seek to improve the SIR performance of receivers, wireless system providers employ coding techniques such as forward error correction (FEC). FEC allows the receiver to locally reconstruct packets corrupted by bit errors without forcing retransmissions [8]. This scheme works by chopping frames into a smaller number of *codewords* and inserting a series of parity bits into each codeword that helps the receiver recover from a small number of bit errors; the greater the number of parity bits, the greater the recovery ability. Inherent in FEC, therefore, is a tradeoff between efficiency and resiliency. A resilient codeword contains more parity bits than does a less resilient one and thus has more transmission overhead, that is, less efficient use of the limited bandwidth. On the other hand, a less resilient code has a higher probability of unrecoverable error and can lead to retransmissions. This is detrimental in both efficient use of bandwidth and delay performance. Typical coding rates—the ratios of information bits to the total size of the codeword—used in wireless systems are usually on the order of $\frac{1}{4}$ to $\frac{2}{3}$. Some systems even offer dynamic FEC coding strategies that change the coding rate on the basis of the perceived error characteristics of the channel. The proper use of FEC techniques, therefore, can improve the integrity of the transmission sequence and reduce delays incurred on error-prone wireless links by reducing retransmissions.

The effectiveness of FEC coding is improved by interleaving [9]. Often wireless channels do not exhibit statistically independent error properties from one bit to the next. This means that bit errors tend to be lumped together in bursts. FEC codes can correct only a small number of errors per codeword. As such, they can be ineffective when dealing with very bursty error channels. Interleaving works to scramble the bit orderings before transmission and then place them back in proper order at the receiver before decoding. Thus bits that travel consecutively over the air will not be consecutive when presented to the FEC decoder. When deep fades corrupt a series of bits in transit, the interleaving process at the receiver will disperse those errors throughout the frame over multiple codewords, improving the effectiveness of the FEC scheme. This again implies that more packets can be corrected without retransmissions thereby reducing delay.

Another FEC technique employed in wireless voice systems to ensure good-quality characteristics is unequal error protection [10]. Unequal error protection is the practice of classifying certain bits in the voice frame as more important than other bits. If such essential bits are corrupted in transmission, then the frame cannot be used because too much fundamental information about the voice sample will have been lost. These bits, as a result,

are protected with FEC codes while the others are not. The nonessential bits in the voice sample can be delivered to the higher layers even if they contain bit errors. Although this reduces the sound quality of the voice sample, the end effect is still tolerable for the listener. The benefit of this approach is twofold: (1) the overhead associated with FEC coding is reduced and (2) usable (albeit less-than-perfect) voice information is delivered in cases where it would otherwise have been dropped or retransmitted.

In order to combat jitter and ensure smooth playback, real-time media systems buffer received voice packets. This solution to combat poor delay performance exists in both the wireless and wired telephone systems. With a buffered voicestream the receiver presents packets to the decoder at regular intervals even if they arrive at irregular intervals. Buffering at the receiver also helps establish correct packet ordering by allowing the receiver to collect a number of unordered packets and place them in the proper sequential order before they are played. This concept is illustrated in Fig. 1. Jitter buffers, however, add to the one-way delay already incurred due to packet encoding and transmission. Jitter buffer lengths must be designed with this delay penalty in mind. The International Telecommunications Union (ITU) states that one-way delay for voice samples must be lower than 400 ms for acceptable voice quality for almost all applications (with the exception of certain long-haul satellite communications). Furthermore, the ITU recommends that delays be below 150 ms [11]. Jitter buffer lengths are an important piece of the overall delay budget that includes codec, medium access, network, and transmission delays.

In addition to these techniques, all 3G systems will also have advanced methods for guaranteeing dataflows greater degrees of access to their air interfaces. Most notably these include forms of traffic classification and priority scheduling at the MAC layer that can dedicate resources to real-time packet streams [12]. These guarantees often provide a minimum bit rate and/or delay. Additionally, they provide intelligent voice-friendly queue management policies. The UMTS, in particular, has specified two real-time traffic classes, *conversational* and *streaming* [13]. The conversational class is the most delay-sensitive and is expected to handle wireless IP telephony. Certain deliverability attributes are associated with each class, such as maximum and guaranteed bit rates, maximum transfer delays, handling priorities, and whether packets with errors should be forwarded to higher layers. Using these attributes to define the service quality requirements for various traffic flows will allow 3G

wireless systems to service time-sensitive voice packets before delay-tolerant data packets.

3.1.2. Transport-Layer Solutions. While these link-level improvements will go a long way toward improving the service quality of wireless voice, performance is also highly dependent on the transport protocols used to deliver samples from the mobile terminal to their final destination. Reliable end-to-end transport protocols that promise ordered delivery of error-free packets, such as *Transmission Control Protocol* (TCP) [14], respond to link-level errors by requesting retransmissions. Such retransmissions hold up the timely delivery of subsequent packets. Furthermore, TCP operates on a principle that packet loss is due to congestion in the network and will thus respond to errors on the channel by generating less traffic. TCP will at first throttle the bit rate and then slowly increase it as the signs of congestion dissipate. This has dire consequences on the performance of voice applications by slowing down the service unnecessarily and imposing unacceptable delays. These issues are further exacerbated in wireless networks where link-level errors are frequent and seldom the result of congestion. It is clear that the application and performance characteristics of wireless voice are at odds with the design goals of TCP. The emphasis on timely delivery of voice over error-free reception cannot be reconciled with the TCP design philosophy, which sacrifices delays to achieve an error-free result.

As a result, the use of TCP to carry wireless voicestreams is not likely. User Datagram Protocol (UDP) [15], the connection-less alternative to TCP, in conjunction with the Real-Time Transport Protocol (RTP) [16], will be the most prominent implementation of voice over IP. UDP requires no retransmissions and is not session based, meaning that it carries no state and treats each packet individually independent of packets before or after it. This statelessness is not necessarily well suited for isochronous media where many packets are often carried with similar characteristics in a stream and it is advantageous to make use of state information. However, protocols such as RTP, which are used in conjunction with UDP, provide functionality to real-time voice above what simple UDP can provide.

RTP was developed to use the basic UDP datagram in order to provide end-to-end support for time-sensitive applications. RTP offers no congestion control and no promises of reliability; however, in the world of voice this is a boon. Without reliability and congestion control, the transport protocol will not mistake link-level errors for congestion and will not delay packets while waiting for retransmissions. End devices can use the information provided in RTP packets to determine the real-time characteristics of the received packet. RTP provides a timestamp field that allows receivers to determine whether an incoming packet is "fresh" and should be played or is "stale" and should be dropped. Sequence numbers are used to identify gaps in the reception of packets. This may signal that an error has occurred or that packets have been received out of order. RTP provides the necessary information to the receiver to

Figure 1. Jitter buffering.

reconstruct the original stream when packets are received out of sequence. RTP is also particularly well suited for delivering multimedia traffic and provides mechanisms by which media streams can be synchronized and multiplexed, such as audio and video for a videoconference. RTP is by far the most frequently used protocol in the wired Internet for transferring real-time information. Because of its widespread use and special features designed for real-time traffic, RTP is the natural transport protocol for wireless IP telephony.

Wireless IP telephony providers must strive to offer service qualities that are comparable to the cellular voice services that customers are accustomed to. Strict requirements on delay, jitter, and packet loss create a challenge in ensuring service quality. In addition to intelligent service quality management of wired backbone links, this challenge will have to be met by coordinated efforts between radio-level mechanisms operating over the wireless link and transport protocols operating end to end.

4. EFFICIENCY AND WIRELESS IP TELEPHONY

Wide-area wireless channels typically employ bandwidths much smaller than those found on landline networks. Furthermore the unpredictable nature of the wireless channel makes the use of small link-level packet sizes advantageous. Small packet sizes are less vulnerable to channel fluctuations and help the radio network recover more gracefully from packet losses. As an example, typical cellular systems today, as well as future 3G systems, employ basic packet sizes that are on the order of 20 ms.

These small packet sizes represent a major challenge to the use of IP-type protocols that employ large headers. The resulting overhead can have detrimental effects on the efficiency of the system. Efficient use of wireless resources allows service providers to support higher capacities. For

wireless IP telephony providers to match the level of spectral efficiency of traditional cellular networks, the resultant overhead of IP transport must be reduced. Header compression techniques are the most effective way to reduce IP packet overheads, and several such compression schemes have been defined for compressing a variety of protocol types. Below we discuss the most relevant aspects of header compression to wireless IP telephony.

4.1. Header Compression

As indicated earlier, voice over IP networks will be supported by the Real-Time Transport Protocol, which runs over UDP. Thus the typical protocol layering for IP voice looks like RTP/UDP/IP.³ Each of these protocols introduces its own overheads in the form of required headers. Typically this value totals 40 bytes, including 20 bytes for RTP, 8 bytes for UDP, and 12 bytes for IP. The protocol header fields for RTP/UDP/IP are shown in Fig. 2, where the numbers represent bit positions and are used to indicate the length of the header fields. We discuss only a few of the header fields below; for more detailed information on the RTP/UDP/IP header fields the reader is referred to the literature [1,15,16].

This 40-byte RTP/UDP/IP overhead represents a significant portion of available wireless bandwidth. Current wireless voice packetization schemes, including

³ This is taken to mean that RTP is on top of UDP, which is on top of IP, indicating that a packet must travel down the protocol stack, traversing first the RTP layer, then the UDP and IP layers. Other references write the protocol layering as IP/UDP/RTP, indicating that IP is outside UDP that is outside RTP. This latter notion emphasizes that IP protocol headers are followed by UDP and RTP protocol headers.

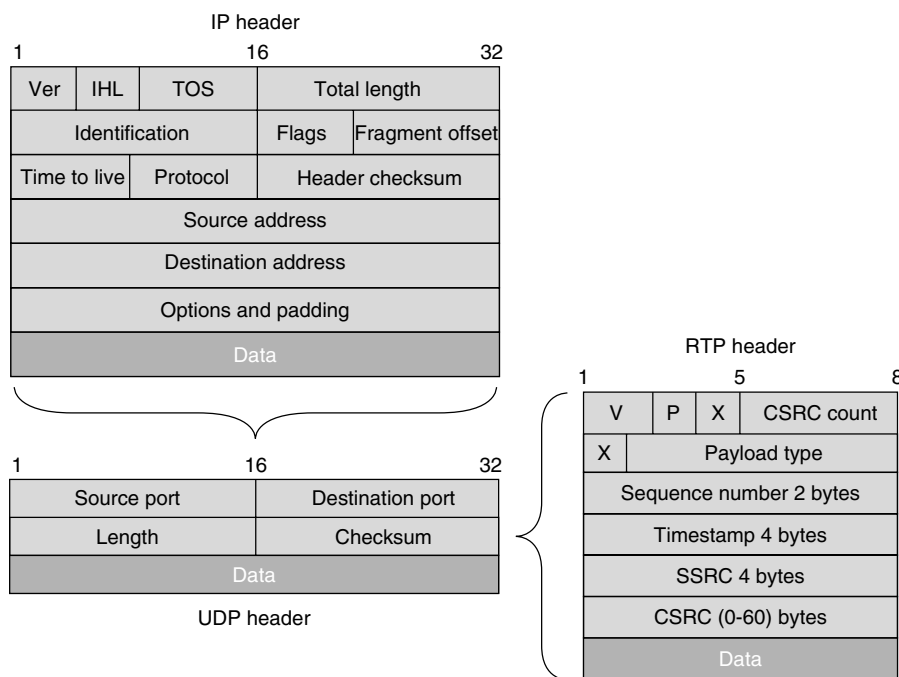

Figure 2. RTP/UDP/IP protocol headers.

the ITU standard G.729 [17], employ 8-kbps codecs where 20 bytes of voice information is sent every 20 ms. Therefore voice packets carried under the RTP/UDP/IP regime will incur a 200% overhead price. Clearly deep RTP/UDP/IP header compression is required for wireless IP telephony to achieve the efficiency that cellular operators need to service a growing number of subscribers.

4.1.1. Compression State. Header compression works on the principle that many RTP/UDP/IP packet header fields change either predictably or very infrequently from packet to packet. For example, the IP addresses of the two correspondents never change during the course of a typical session; however, the 64 bits (8 bytes) used to denote source and destination IP addresses, is included in each UDP header. A similar situation exists for the source and destination port addresses, which account for 2 bytes. Addressing and port assignments, which remain largely static over the lifetime of a call, account for roughly 25% of the total overhead. Header compression schemes leverage the predictability of packet headers from packet to packet to achieve compression levels on the order of 95–97%; in some instances they reduce 40-byte overhead to 1 or 2 bytes.

Header compression schemes are able to achieve these levels of compression by first eliminating well-known a priori information or information that can be inferred from other mechanisms, such as the link layer. Fields such as the IP and RTP version numbers are expected to be well known, other values such as the IP header and payload lengths can be successfully inferred from the link layer. Moreover, sending non-a priori, but static, information only once at the onset of the session reduces overhead considerably. Values such as the abovementioned 8-byte IP addresses and 2-byte port numbers, among others, can be sent once and will remain constant over a large number of packet headers. Sending these values once helps the compressor and decompressor establish a *context*, or compression state, by which future compressed packets can be evaluated. Compression state is the knowledge necessary to reconstitute the full header from a compressed header. After the initial sending, it is necessary to only provide delta values, or updates, in header fields that change instead of the absolute values. This significantly reduces the amount of overhead transmission.

Figure 3 shows the general architecture of a header compression scheme where a *compressor* takes full RTP/UDP/IP headers and generates compressed headers that are sent over the wireless channel. On the receiving side the decompressor attempts to reconstruct the original header by applying the corresponding decompression scheme using the current header context. When the context becomes lost or loses synchronization between the compressor and the decompressor, as is the result of link-layer errors, the compression scheme must be able to restore context.

4.1.2. Error Recovery. An important consideration in the design of a header compression scheme for the wireless environment is its ability to recover from errors. Cassner

Figure 3. Header compression architecture.

and Jacobson proposed the earliest header compression technique for RTP/UDP/IP, *compressed RTP* (CRTP), [18] which became a draft standard in 1999. While this scheme worked well for telephone dialup connections and other low-loss link layers, its design did not perform well in a highly variable and error-prone wireless channel. When packets were received in error, the header compression states at the compressor and the receiver would lose context and full packet headers had to be transferred to reestablish synchronized header state. The effect of long round-trip times, as is the case with wireless IP telephony, has dramatic effects on the error recovery performance. When links have long round-trip times the context cannot be regained as quickly and many compressed packets will require retransmissions or be dropped. Performance lags in CRTP over wireless links became evident [19], and efforts were made to design more robust header compression schemes that could adapt to imperfections in the channel and gracefully recover from errors.

4.1.3. Robust Header Compression. To meet the error performance requirements necessitated by volatile wireless links, header compression schemes have to be reliable and robust. The *robust header compression* (ROHC) scheme [20] was created to make header context less sensitive to packet loss and delay as well as make context recovery faster. This approach repairs context locally, thereby eliminating the need to send update information over the wireless link.

The key factor in ROHC is that cyclic redundancy check (CRC) codes are computed on the uncompressed headers and are sent along with the compressed header. CRC codes are the result of passing a string of bits through a generator polynomial. The CRC codes are then sent along with the bits used to generate the codes. The receiver applies the same function to the received bit string, generating a local copy of the CRC code. If the local copy and the received CRC code are not equal, the receiver is sure that a transmission

error has occurred. CRC codes provide a reliable error-detection mechanism. The decompressor, after generating its copy of the full header from the received compressed header, will perform a CRC check on the full header. This allows the decompressor to reliably determine whether the decompression process was successful. In addition to being able to repair context locally, ROHC is also capable of withstanding a number of consecutive packet errors without losing context. This is important as wireless environments seldom have bit-independent channels and errors often arrive in bursts. ROHC can support upwards of 24 consecutive packet errors without losing context [21].

4.1.4. Performance of Header Compression. Header compression schemes can be evaluated along three distinct performance attributes: compression efficiency, robustness, and compression reliability. In terms of compression efficiency, ROHC can optimally reduce the 40-byte RTP/UDP/IP header to a single byte. Under bit error rates typical of wireless channels, it can achieve an average of 2.27 bytes of overhead [22]. Furthermore, compression efficiency is enhanced by the ability to restore context locally, reducing the transmission of noncompressed headers over the wireless link. Compression reliability, the ability to ensure that decompressed headers are accurate representations of the uncompressed headers, is achieved through the use of CRC codes. This provides a highly reliable way for the decompressor to determine whether the decompressed packet is correct. Finally, ROHC provides a high degree of robustness by correcting loss of context locally and maintaining context in the presence of multiple consecutive errors. Performance results [22] show that under a simulated WCDMA channel operating at a BER of 0.0002 the FER achieved with CRTP is 1.10% while the FER achieved with ROHC was 0.12%. At a higher BER value of 0.001, the frame error rates were 4.06% and 0.81% for CRTP and ROHC, respectively.

It is clear that this new class of robust header compression will be critical to improving the efficiency and performance of wireless IP telephony.

5. MOBILITY

Mobility creates problems with IP routing protocols and can break ongoing sessions. However, wireless IP telephony must be as seamless as present cellular telephony. This requires the ability to change points of attachment to the wireless network while maintaining connectivity with minimal disruption. Cellular solutions address mobility by monitoring channel assignments, code allocations, and received power levels. The introduction of IP transport, however, requires additional mobility solutions that are not addressed by the traditional link-layer cellular mobility techniques. These requirements for *network* mobility extend beyond the *physical*, or *link-level*, mobility offered in cellular networks. The basic functions needed to support mobile access to IP-based networks include

- *Detection*—terminals learn when they have entered new network areas.
- *Registration*—users indicate their presence and requirements to the network.
- *Configuration*—network adapts nodes to the particular network characteristics, including IP address assignment and configuration of the default router.
- *Authentication, authorization, and accounting (AAA)*—validate users and their permission and record their usage for billing and management purposes.
- *Dynamic address binding*—provides a dynamic mapping of old network addresses with new network addresses.

To become a full network participant a user must first have means of physically detecting and connecting to a network. This entails establishing a valid link with the appropriate physical layer protocols, after which a terminal can format information in a contextually meaningful manner. When basic connectivity has been established the mobile and the network can begin to perform parameter negotiations. This occurs during the registration process where the network learns of a terminal's presence and requirements.

Configuration involves fulfilling any registration requests and providing information to enable the mobile to properly orientate itself to the new network surroundings. This may include assigning a new IP address and passing the locations of default routers and network servers. After configuration the next step is for the network to grant the user access to network resources based on AAA measures. The network arrives at these decisions based on negotiations using credentials passed between the terminal and/or user, either explicitly or implicitly. Additionally the network may validate these credentials with third parties located in outside networks. Finally, once the user and terminal have been properly authenticated, dynamic address binding creates an association between the new configuration and the old configuration. This allows mobile terminals to be found after they change networks and allows active sessions to be maintained across different points of attachment transparently.

5.1. IP Mobility for Wireless Telephony

Current cellular networks have mechanisms in place to successfully support link-level mobility. Additionally roaming agreements between service providers allow mobile subscribers from one provider to access another provider's network. In this sense, current cellular networks already have in place mechanisms to support registration, configuration, and AAA functions associated with mobility. However, since mobile telephone numbers are constant and do not change, there is no need to perform dynamic address binding. Also since addressing is valid over the entire network, there is no need to detect when an address change is required. Therefore detecting when address changes are required and dynamically binding those addresses represents a major challenge for current cellular networks to provide mobility.

Supporting dynamic address binding for wireless IP telephony users poses some unique challenges. The IP protocol inherently links physical location with network

representation. In other words, an IP address represents a host's physical location on the network as well as its identity within the network. IP uses this association to route packets efficiently to destination addresses. When this association is broken, or invalid, packets can no longer reach their destinations.

5.2. Mobile IP

The industry standard regarding IP mobility is called *mobile IP* [23] and is actively being designed into the all-IP architectures of next-generation networks including the 3GPP and the 3GPP2 [24]. Mobile IP creates a level of indirection within the network so that on-going communications are not interrupted due to the IP address changes of mobile terminals. This is achieved by associating two addresses for the mobile terminal: a permanent *home address* that represents the terminal's IP address within its home network and a temporary locally assigned *care-of address* that is valid within the visited network. A *home agent* (HA) located in the terminal's home network keeps an association between a terminal's home address and its care-of address. A *foreign agent* (FA) in the visited network provides routing and support services to visiting mobile terminals. The elements of a typical Mobile IP architecture are depicted in Fig. 4.

Both foreign and home agents can advertise their presence on their respective local networks by issuing agent advertisement messages that inform terminals of their availability. Likewise, a mobile terminal may solicit these messages by broadcasting agent solicitation messages on entering a new network to learn about that network's mobility support. A mobile terminal can then use these advertisement messages to detect if it has migrated into a new IP subnet.

Once a mobile terminal learns that it is on a new IP subnet, it will attempt to obtain a care-of address for the visited subnet. This can be done in one of two ways. It may be given a care-of address by the FA, called a

foreign agent care-of address, which is associated with a network interface on the FA. The mobile terminal may also obtain a *collocated care-of address* associated with one of its own network interfaces. After receiving the care-of address, the mobile terminal will then register this address with its HA via a registration request message. When this registration is accepted, the HA will respond with a registration response message and store the association between the mobile terminal's home address and care-of address.

Packets that are destined for the mobile terminal, that is, those that have the mobile terminal's home address in the destination field of the IP header, always arrive inside the mobile terminal's home network and are intercepted by the HA. The packets are then *tunneled* to the mobile terminal by the HA. The tunneling process involves encapsulating [25] the sender's original IP packet inside the body of another IP packet generated by the HA that contains the mobile terminal's care-of address in the destination field. Since the outer header of the encapsulated IP packet contains the care-of address, it will be forwarded to the visited network where the mobile terminal currently resides. When foreign agent care-of addresses are used, the tunneled packets arrive at the FA who decapsulates them by stripping off the encapsulated packet header and sends the original IP packet to the mobile terminal. Mobile terminals that have collocated care-of addresses will receive incoming encapsulated packets directly and be responsible for decapsulating them.

Bandwidth-constricted wireless networks will most likely support the foreign agent care-of address model, as is the case with the 3GPP and 3GPP2. This mode of operation is more spectrally efficient since only the original IP packet, and not the extra headers associated with the encapsulated packet, is sent over the air interface. Additionally this mode conserves IP address space; one FA can service multiple mobile terminals, and therefore only one care-of address per FA is needed.

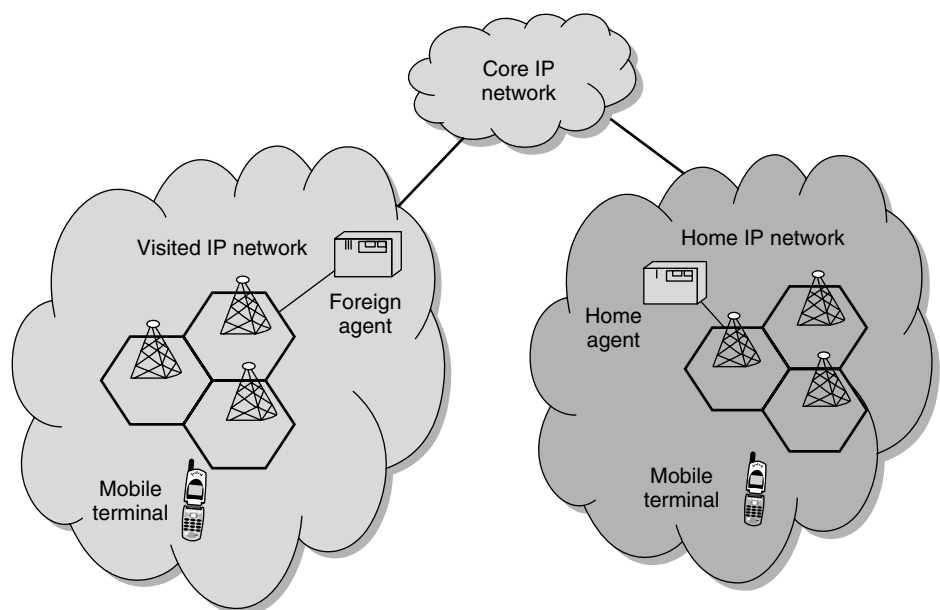

Figure 4. Mobile IP architecture.

The mobile terminal can send outbound IP packets on the visited network using normal IP routing without any modifications. The mobile terminal will insert its home address into the source address field of all IP data packets it generates. The mobile IP agents effectively hide mobility events from correspondent hosts so that IP address changes are transparent. Thus correspondent hosts are completely unaware that the mobile terminal has moved. This feature of mobile IP allows all network terminals, regardless of whether they support mobile IP, to communicate with mobile terminals that do.

5.2.1. Route Optimization. Mobility implementations in wireless IP telephony are judged on their ability to provide seamless handoffs with minimal interruption to user sessions. Packet loss and handoff delay therefore must be minimized in order to provide quality voice service. A vulnerability of the basic mobile IP approach discussed above is that traffic streams are required to go to the mobile terminal's HA and then to the mobile terminal, creating what is called the *triangular routing problem*. This is particularly problematic when a mobile terminal is very far from its home network and is communicating with a correspondent host local to the visited network as shown in Fig. 5. As an example, consider a New Yorker visiting a friend in Los Angeles. Packets from the friend's terminal would have to travel across the country to the HA in New York and then be tunneled back to the present location of the mobile terminal in Los Angeles. This needlessly introduces two cross-country trip times.

In addition, it consumes unnecessary resources within the wide-area network, especially when compared to direct delivery on the local Los Angeles network. Efforts within the mobile IP community have addressed this problem by creating a modified mobile IP approach that uses route optimization [26] and eliminates unnecessary triangular routing.

Route optimization works by making correspondent hosts aware of the current care-of address of the mobile terminal. The host then stores those associations in a binding cache. Home agents, on receipt of a packet destined for a mobile host in a visited network, will send the originator of that packet a message containing the mobile terminal's current care-of address. The originator will then store this association in its binding cache and can begin to send packets directly to the mobile host without unnecessary involvement of the HA. This, in turn, reduces latency and frees network resources. Implementing route optimization in mobile IP can help drastically eliminate latencies and improve quality for wireless IP telephony.

5.3. Mobility Architectures

A design challenge for implementing mobile IP in wireless environments is to define proper placement and demarcations of areas serviced by the mobile IP elements. This helps balance signaling overhead and delay while allowing seamless connectivity. Advertisement and solicitation messages generated in mobile IP are a way of determining whether new physical connections

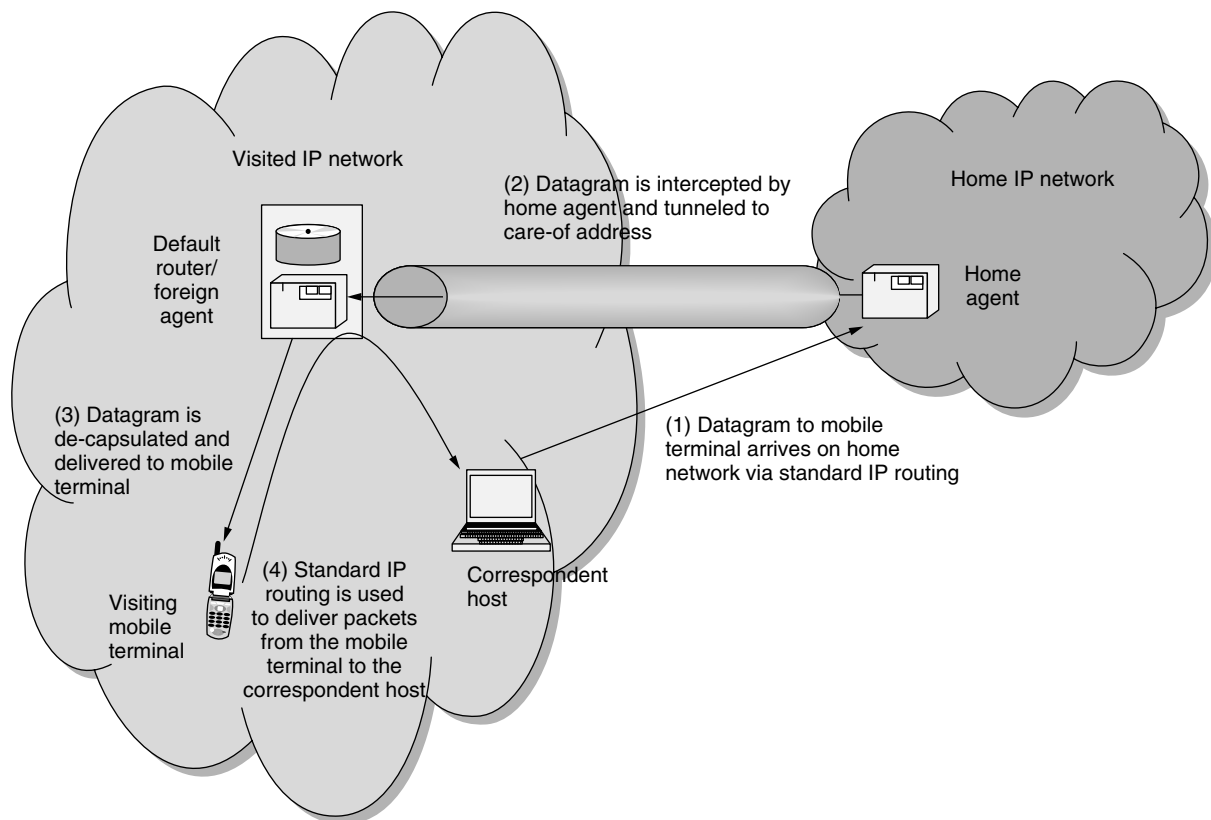

Figure 5. Mobile IP triangular routing.

require IP-level mobility procedures. However, when cell radii decrease and terminals travel at higher speeds, the mobility rate increases. This triggers more and more solicitation and registration messages that could begin to have a detrimental overhead effect in the network. Furthermore, the registration messages must travel to the mobile terminal's home network and may introduce unacceptable delays in establishing new network connections. Designing wireless networks with subnets that do not cover a lot of area may lead to an undesirable amount of signaling and delay in current mobile IP implementations.

Additionally, mobile agents need to balance the frequency with which they broadcast advertisements to suit the signaling capabilities of the wireless network. More frequent signaling allows for faster detection of network-layer mobility and therefore shorter handoff times. It comes, however, at the price of greater signaling overhead. There exists a design tradeoff that trades signaling overhead for responsiveness of the mobility protocol. As radio-level resources are at a premium, optimal solutions will employ as little signaling overhead as possible to achieve the required level of responsiveness.

Industry efforts have been focused on this problem, and new breeds of mobility strategies have emerged that attempt to reduce the delays and overhead caused by excessive signaling and frequent mobility [27–29]. Many of these strategies introduce levels of hierarchy so that registration messages do not need to travel all the way to the home network every time there is a mobility event. These types of strategies help reduce the latencies and packet losses due to IP mobility.

6. CONCLUSION

Since 1980 wireless voice service has grown into a reliable mainstay for personal and business communications. In the same period the Internet has flourished to unprecedented levels; enjoying economies of scale and ease of deployment. New wireless network architectures will take advantage of the service and management flexibility offered by IP, allowing service providers to offer multimedia and data content to their wireless subscribers. As a consequence, voice strategies must be amended from their traditional circuit-switched roots to perform comparably over IP. The greatest challenges facing the successful deployment of wireless IP telephony are threefold: securing reliable guarantees of service quality on par with traditional cellular systems, obtaining spectral efficiencies over the wireless channel that will not hinder system capacity or service quality, and effectively providing seamless connections to mobile users.

BIOGRAPHY

David Famolari received his B.S and M.S degrees in electrical engineering from Rutgers University, New Jersey, in 1996 and 1999 respectively. In 1996, he joined the Wireless Information Network Laboratory (WINLAB), at Rutgers University, as a research assistant where he worked on

radio resource management protocols and parameter optimizations for third generation (3G) cellular systems. Since 1998, he has been a member of the Applied Research Department at Telcordia Technologies, Morristown, New Jersey, where he has worked on emerging mobile computing technologies, wireless networking protocols, and residential networking. David was awarded the Telcordia Technologies CEO Award in 2000 for his contributions in wireless IP networking. He is currently the cochair of the Open Services Gateway Initiative (OSGi) Device Expert Group, a leading industry consortium producing open specifications to promote the delivery of broadband services into home, automotive, and other similar networks. His current research interests include wireless local area network (WLAN) technologies and systems, mobility management, wireless computing, and personal area networks and systems. He can be reached by e-mail at fam@research.telcordia.com.

WIRELESS LAN STANDARDS

RICHARD VAN NEE
Woodside Networks
Breukelen, The Netherlands

1. INTRODUCTION

Since the early 1990s, wireless local-area networks (WLANs) for the 900-MHz, 2.4-GHz, and 5-GHz ISM (industrial–scientific–medical) bands have been available for a range of proprietary products. In June 1997, the Institute of Electrical and Electronics Engineers approved an international interoperability standard (IEEE 802.11 [1]). The standard specifies both medium-access control (MAC) procedures and three different physical layers (PHY). There are two radio-based PHYs using the 2.4-GHz band. The third PHY uses infrared light. All PHYs support a data rate of 1 Mbps (megabit per second) and optionally 2 Mbps. The 2.4 GHz band is available for license exempt use in Europe, the United States and Japan. Table 1 lists the available frequency

Table 1. 2.4- and 5-GHz Bands

Location	Regulatory Range (GHz)	Maximum Output Power
North America	2.400–2.4835	1000 mW
Europe	2.400–2.4835	100 mW (EIRP ^a)
Japan	2.400–2.497	10 mW/MHz
USA (UNII lower band)	5.150–5.250	Minimum of 50 mW or 4 dBm + 10 log ₁₀ B ^b

bands and the restrictions to devices that use this band for communications.

User demand for higher bit rates and the international availability of the 2.4-GHz band has spurred the development of a higher-speed extensions to the 802.11 standard. In 1999, the IEEE 802.11b standard was finished, and describes a PHY providing rates of 5.5 and 11 Mbps [2]. IEEE 802.11b is an extension of the direct-sequence 802.11 standard, using the same 11 MHz chip rate, such that the same bandwidth and channelization can be used.

In parallel to IEEE 802.11b, the IEEE 802.11a standard was developed to provide high bit rates in the 5-GHz band. This development was motivated by an amendment to Part 15 of the U.S. Federal Communications Commission in January 1997. The amendment made available 300 MHz of spectrum in the 5.2-GHz band, intended for use by a new category of unlicensed equipment called “unlicensed national information infrastructure” (UNII) devices. Table 1 lists the frequency bands and the corresponding power restrictions.

In July 1998, the IEEE 802.11 standardization group decided to select orthogonal frequency-division multiplexing (OFDM) [3] as the basis for their new 5-GHz standard, targeting a range of data rates from 6 to 54 Mbps. This standard is the first one to use OFDM in packet-based communications, while the use of OFDM previously was limited to continuous transmission systems like digital audiobroadcasting (DAB) and digital videobroadcasting (DVB). Following the IEEE 802.11 decision, the European HIPERLAN type 2 [4] standard and the Japanese Multimedia Mobile Access Communication (MMAC) standard also adopted OFDM. The three bodies have worked in close cooperation since then to minimize differences between the various standards, thereby enabling the manufacturing of equipment that can be used worldwide.

Regulatory issues played an important role in the development of wireless LAN standards. One of the key factors in the choice of modulation schemes for the 2.4-GHz band has been the FCC spreading requirement for unlicensed devices in the ISM bands, where wireless LANs

are predominantly used. According to the FCC spreading rules, transmission in the ISM bands have to use either direct sequence, spread spectrum, or frequency hopping. Frequency-hopping devices have to use at least 75 hopping channels with a maximum dwell time of 400 ms. Direct-sequence devices have to demonstrate at least 10 dB processing gain in a narrowband jammer test, which basically shows that there is a gap of at least 10 dB between signal-to-noise ratio and signal-to-interference ratio requirements for a certain bit error ratio. In the early days of wireless LAN, many people interpreted the spreading rule as a requirement for at least 10 chips per symbol; hence the 11 chips spreading sequence in the 802.11 standard. Later, a less strict interpretation was adopted, purely based on meeting the narrowband jammer test. This is clearly visible in the IEEE 802.11b standard. The 802.11b standard uses complementary code keying (CCK), which can be viewed as direct-sequence spread-spectrum modulation with multiple spreading codes with a length of 8 chips. Despite the less strict interpretation, the spreading rule formed a barrier for really high data rates. It blocked the use, for instance, of OFDM in the 2.4-GHz band. In order not to avoid further technological progress in the 2.4-GHz band, in May 2001 the FCC decided to allow digital transmissions without any spreading requirement [5]. This opened the way to higher data rates using OFDM in the 2.4-GHz band. The 802.11 committee took advantage of this rule change by selecting the OFDM based 802.11a standard as basis for the 802.11g standard, extending the data rates in the 2.4-GHz band up to 54 Mbps.

In the following sections we describe the various IEEE wireless LAN standards, and mention the differences with HIPERLAN and MMAC. Because of length limitations, the scope of this article is restricted to the most predominantly used parts of the standards. More details can be found in the references listed at the end of this article.

2. IEEE 802.11 MAC

The IEEE 802.11 MAC standard consists of one mandatory and two optional modes [1]. All modes use time-division duplex (TDD), so the medium is shared in time between different users and/or access points. The mandatory part is the *distributed coordination function* (DCF), which uses carrier sense multiple access with collision avoidance (CSMA/CA). Figure 1 shows the timing diagram of a DCF packet transmission. Before starting a transmission, the channel is sensed to see if it is available. If no other signal is received above a certain defer threshold, a packet is sent. After successful reception, the recipient sends an acknowledgment back. After receiving the acknowledgement, the first user has to

wait for a time DIFS plus a random backoff time before transmitting another packet. DIFS is the *distributed interframe spacing*, which is equal to the *short interframe spacing* between packet and acknowledgment plus 2 slot times.

Optional modes in the 802.11 MAC are the request-to-send/clear-to-send (RTS/CTS) protocol, and the point coordination function (PCF). PCF is a centralized MAC, where an access point polls stations to see if they have packets to transmit. PCF can be used to guarantee a minimum packet delay, but it can do this only in the absence of interference from other cells. With the RTS/CTS protocol, prior to a data packet, first a short request packet is sent. The receiver answers with a CTS packet, which contains a net allocation vector (NAV) that tells all users how long the current RTS/CTS cycle will take. The effect of this is that all users that can receive the CTS packet will not try to try to compete for the channel for the duration indicated by the NAV. This solves the hidden-node problem of DCF without RTS/CTS, because in that case, only users that can receive the transmitter will stop competing for the channel. So, it can happen that a packet from user A to B is interfered by user C, who does not have a good link to A, but it does have a good link to B. With RTS/CTS, this situation is avoided, because user C will hear the CTS coming from B.

3. IEEE 802.11 DSSS

The IEEE 802.11 Direct-Sequence Spread-Spectrum standard is based on the transmission of 11-chip Barker codes at a 11 MHz chip rate. Data rates of 1 and 2 Mbps are achieved using BPSK or QPSK modulation of the Barker codes, respectively. The 11-chip Barker code is defined as $\{1, -1, 1, 1, -1, 1, 1, 1, -1, -1, -1\}$. Its primary use is to satisfy the FCC spreading requirements, as well as providing robustness against multipath propagation and narrowband interferers. Robustness against multipath is obtained by the ideal aperiodic autocorrelation properties that define a Barker code—a *Barker code* is a code for which the absolute autocorrelation sidelobes are equal to or less than one (≤ 1) for all nonzero delays, compared to L for a zero delay, where L is the codelength. Because of the low-autocorrelation sidelobes, effects of intersymbol interference are greatly suppressed, while a simple RAKE receiver is able to significantly benefit from multipath diversity in frequency selective channels.

The 802.11 packet structure is shown in Fig. 2. The complete packet (PPDU) has three segments. The first segment is the preamble, which is used for signal detection and synchronization. The second segment is the header, which contains data rate and packet length information. The third segment (MPDU) contains the information bits.

Figure 1. Timing diagram of a single-packet transmission using DCF.

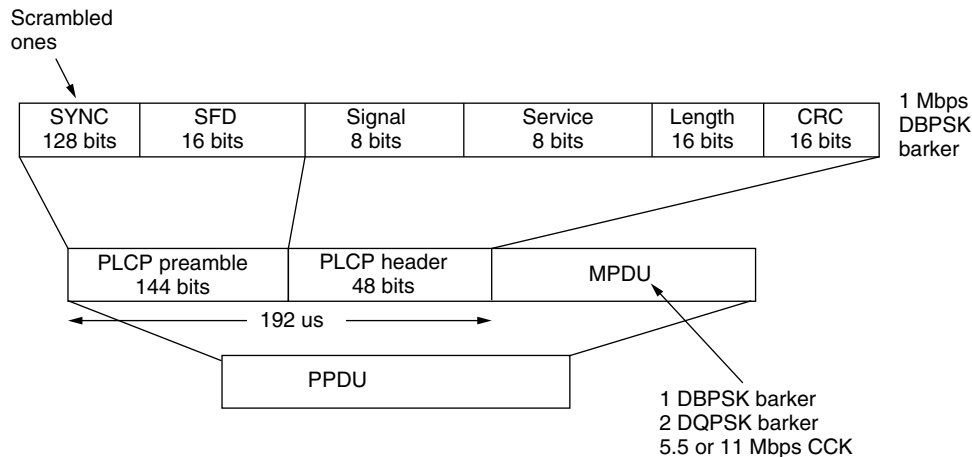

Figure 2. The packet structure used for 802.11 DSSS 1 and 2 Mbps, with the extension to 5.5 and 11 Mbps shown.

The preamble and header are transmitted at 1 Mbps, while the data portion is sent at one out of four possible rates.

The preamble is formed from a SYNC field and a SYNC field delimiter (SFD). The SYNC field is generated using 128 scrambled ones. The SYNC field is used for clear channel assessment, signal detection, timing acquisition, frequency acquisition, multipath estimation, and descrambler synchronization.

4. IEEE 802.11b

In July 1998, the IEEE 802.11b working group adopted complementary code keying (CCK) as the basis for the high-rate physical-layer extension to deliver data rates of 5.5 and 11 Mbps [6]. This high-rate extension was adopted in part because it provided an easy path for interoperability with the existing 1- and 2-Mbps networks by maintaining the same bandwidth and utilizing the same preamble and header as shown in Fig. 1. An optional short preamble with a 56-bit SYNC field is specified to increase the net data throughput.

Complementary codes were originally conceived by M. J. E. Golay for infrared multislit spectrometry [7]. However, their properties also make them useful in radar applications and more recently for discrete multitone communications and OFDM [8]. The original publication [7] defines a complementary series as a pair of equally long sequences composed of two types of elements that have the property that the number of pairs of like elements with any given separation in one series is equal to the number of pairs of unlike elements with the same separation in the other series. Another way to define a pair of complementary codes is to say that the sum of their aperiodic autocorrelation functions is zero for all delays except for a zero delay.

The CCK codes that were selected as the basis for IEEE 802.11b were first published in 1996 [8]. More background information on these codes can be found in Halford et al. [9]. The following equation represents the 8

complex chip values for the CCK code set, with the phase variables being QPSK phases:

$$c = \{e^{j(\varphi_1 + \varphi_2 + \varphi_3 + \varphi_4)}, e^{j(\varphi_1 + \varphi_3 + \varphi_4)}, e^{j(\varphi_1 + \varphi_2 + \varphi_4)}, -e^{j(\varphi_1 + \varphi_4)}, e^{j(\varphi_1 + \varphi_2 + \varphi_3)}, e^{j(\varphi_1 + \varphi_3)}, -e^{j(\varphi_1 + \varphi_2)}, e^{j(\varphi_1)}\} \quad (1)$$

Basically, the three phases φ_2 , φ_3 and φ_4 , define 64 different codes of 8 chips, where φ_1 gives an extra phase rotation to the entire codeword. Actually, the latter phase is differentially encoded across successive codewords, equivalent to the 1- and 2-Mbps DSSS differential phase encoding. This feature allows the receiver to use differential phase decoding, eliminating a carrier tracking PLL, if desired. Each of the four phases φ_1 to φ_4 represents 2 bits of information, so a total of 8 bits is encoded per 8-chip CCK codeword.

At 5.5 Mbps, the processing is similar. Four information bits are consumed per 8-chip CCK codeword transmission. The codeword rate is still 1.375 MHz, since the chip rate is 11 Mcips/s. Two bits select 1-of-4 CCK subcodes. The other two information bits quadriphase-modulate (rotate) the whole codeword. The 4 CCK subcodes are contained in the larger 64 subcode set of 11 Mbps. At the receiver, the CCK codes can be decoded by using a modified fast Walsh transform as described by Grant and van Nee [10].

5. IEEE 802.11a

IEEE 802.11a provides data rates of 6–54 Mbps in the 5-GHz band using orthogonal frequency-division multiplexing (OFDM). The basic principle of OFDM is to split a high-rate datastream into a number of lower-rate streams that are transmitted simultaneously over a number of subcarriers. Since the symbol duration increases for the lower-rate parallel subcarriers, the relative amount of time dispersion caused by multipath delay spread is decreased. Intersymbol interference is eliminated almost completely by introducing a guard time in every OFDM symbol. In the guard time, the OFDM symbol is cyclically extended to avoid intercarrier interference. Figure 3 shows an example of 4 subcarriers

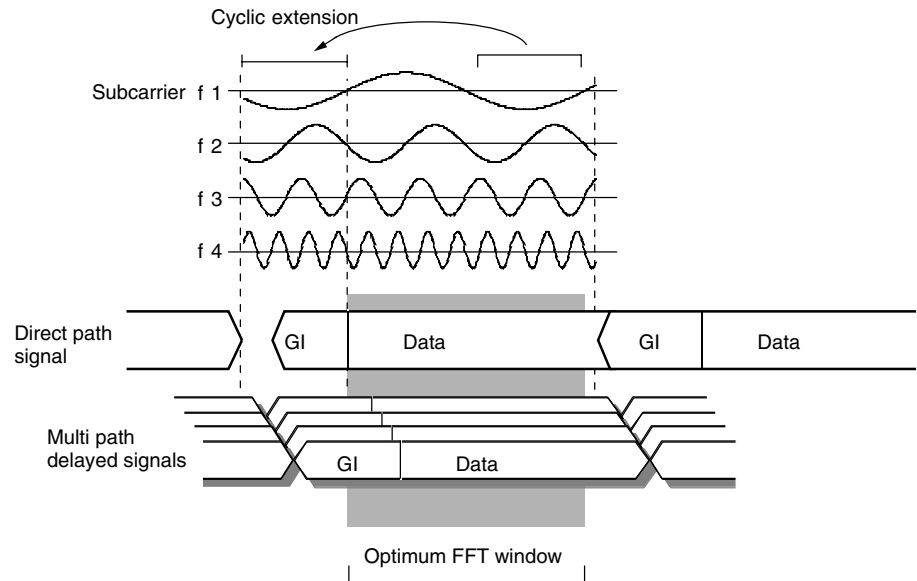

Figure 3. OFDM symbol with cyclic extension.

from one OFDM symbol. In practice, the most efficient way to generate the sum of a large number of subcarriers is by using inverse fast fourier transform (IFFT). At the receiver side, FFT can be used to demodulate all subcarriers. It can be seen in Fig. 3 that all subcarriers differ by an integer number of cycles within the FFT integration time, which ensures the orthogonality between the different subcarriers. This orthogonality is maintained in the presence of multipath delay spread, as illustrated by Fig. 3. Because of multipath, the receiver sees a summation of time-shifted replicas of each OFDM symbol. As long as the delay spread is smaller than the guard time, there is no intersymbol interference nor intercarrier interference within the FFT interval of an OFDM symbol. The only remaining effect of multipath is a random phase and amplitude of each subcarrier, which has to be estimated in order to do coherent detection. In order to deal with weak subcarriers in deep fades, forward error correction across the subcarriers is applied.

5.1. OFDM Parameters

Table 2 lists the main parameters of the IEEE 802.11a OFDM standard. A key parameter that largely determined the choice of the other parameters is the guard interval of 800 ns. This guard interval provides robustness to root-mean-squared delay spreads up to several hundreds of nanoseconds, depending on the coding rate and modulation used. In practice, this means that the modulation is robust enough to be used in any indoor environment, including large factory buildings. It can also be used in outdoor environments, although directional antennas may be needed in this case to reduce the delay spread to an acceptable amount and to increase the range.

In order to limit the relative amount of power and time spent on the guard time to 1 dB, the symbol duration was chosen to be 4 μ s. This also determined the subcarrier spacing to be 312.5 kHz, which is the inverse of the symbol duration minus the guard time. By using 48 data subcarriers, uncoded data rates of 12–72 Mbps can be

Table 2. Main Parameters of the OFDM Standard

Data Rate	6, 9, 12, 18, 24, 36, 48, 54 Mbps
Modulation	BPSK, QPSK, 16-QAM, 64-QAM
Coding rate	$\frac{1}{2}$, $\frac{2}{3}$, $\frac{3}{4}$
Number of subcarriers	52
Number of pilots	4
OFDM symbol duration	4 μ s
Guard interval	800 ns
Subcarrier spacing	312.5 kHz
–3-dB bandwidth	16.56 MHz
Channel spacing	20 MHz

achieved by using variable modulation types from BPSK to 64-QAM. In addition to the 48 data subcarriers, each OFDM symbol contains an additional 4 pilot subcarriers, which can be used to track the residual carrier frequency offset that remains after an initial frequency correction during the training phase of the packet.

In order to correct for subcarriers in deep fades, forward error correction across the subcarriers is used with variable coding rates, giving coded data rates of 6–54 Mbps. Convolutional coding is used with the industry standard rate- $\frac{1}{2}$, constraint length 7 code with generator polynomials (133,171). Higher coding rates of $\frac{2}{3}$ and $\frac{3}{4}$ are obtained by puncturing the rate- $\frac{1}{2}$ code.

5.2. Channelization

For the 200-MHz-wide spectrum in the lower and middle UNII bands, 8 OFDM channels are available with a channel spacing of 20 MHz. The outermost channels are spaced 30 MHz from the band edges in order to meet the stringent FCC-restricted band spectral density requirements. The FCC also defined an upper UNII band from 5.725 to 5.825 GHz, which carries another 4 OFDM channels. For this upper band, the guard spacing from the band edges is only 20 MHz, since the out-of-band spectral requirements for the upper band are less severe than

those of the lower and middle UNII bands. In Europe, the same spectrum as the lower and middle UNII band is available, plus an extra band from 5.470 to 5.725 GHz. In Japan, a 100-MHz-wide band from 5.15 to 5.25 is available. This band contains 4 OFDM channels with 20 MHz guard spacings from both band edges.

5.3. OFDM Signal Processing

The general block diagram of the baseband processing of an OFDM transceiver is shown in Fig. 4. In the transmitter path, binary input data are encoded by a standard rate- $\frac{1}{2}$ convolutional encoder. The rate may be increased to $\frac{2}{3}$ or $\frac{3}{4}$ by puncturing the coded output bits. After interleaving, the binary values are converted into QAM values. To facilitate coherent reception, 4 pilot values are added to each 48 data values, so a total of 52 QAM values is reached per OFDM symbol, which are modulated onto 52 subcarriers by applying the inverse fast Fourier transform (IFFT). To make the system robust to multipath propagation, a cyclic prefix is added. Further, windowing is applied to get a narrower output spectrum. After this step, the digital output signals can be converted to analog signals, which are then upconverted to the 5 GHz band, amplified, and transmitted through an antenna.

The OFDM receiver basically performs the reverse operations of the transmitter, together with additional training tasks. First, the receiver has to estimate frequency offset and symbol timing, using special training symbols in the preamble. Then, it can do a FFT for every symbol to recover the 52 QAM values of all subcarriers. The training symbols and pilot subcarriers are used to correct for the channel response as well as remaining phase drift. The QAM values are then demapped into binary values, after which a Viterbi decoder can decode the information bits.

Figure 5 shows the time-frequency structure of an OFDM packet, where all known training values are marked in gray. It illustrates how the packet starts with 10 short training symbols, using only 12 subcarriers, followed by a long training symbol and data symbols, with each data symbol containing 4 known pilot subcarriers that are used

for estimating the reference phase. The preamble, which is contained in the first 16 μ s of each packet, is essential to perform start-of-packet detection, automatic gain control, symbol timing, frequency estimation, and channel estimation. All of these training tasks have to be performed before the actual data bits can be successfully decoded. More detailed information on OFDM signal processing as well as performance results can be found in Ref. 11.

5.4. Differences Between IEEE, ETSI, and MMAC

The main differences between IEEE 802.11 and HIPERLAN type 2—which is standardized by ETSI BRAN—are in the medium access control (MAC). IEEE 802.11 uses a distributed MAC based on carrier sense multiple access with collision avoidance (CSMA/CA), while HIPERLAN type 2 uses a centralized and scheduled MAC, based on wireless ATM. MMAC supports both of these MACs. As far as the physical layer is concerned, there are only a few minor differences, summarized as follows:

- HIPERLAN uses extra puncturing to accommodate the tail bits in order to keep an integer number of OFDM symbols in 54-byte packets [12].
- In the case of 16-QAM, HIPERLAN uses rate $\frac{9}{16}$ instead of rate $\frac{1}{2}$ —giving a bit rate of 27 instead of 24 Mbps—in order to get an integer number of OFDM symbols for packets of 54 bytes. The rate $\frac{9}{16}$ is made by puncturing 2 out of every 18 coded bits.
- HIPERLAN uses different training sequences. The long training symbol is the same as for IEEE 802.11, but the preceding sequence of short training symbols is different. A downlink transmission starts with 10 short symbols as in IEEE 802.11, but the first 5 symbols are different in order to enable detection of the start of the downlink frame. Uplink packets may use 5 or 10 identical short symbols, with the last short symbol inverted.

6. IEEE 802.11g

The IEEE 802.11g standard extends the 802.11b standard with higher data rates for the 2.4-GHz band [13]. It

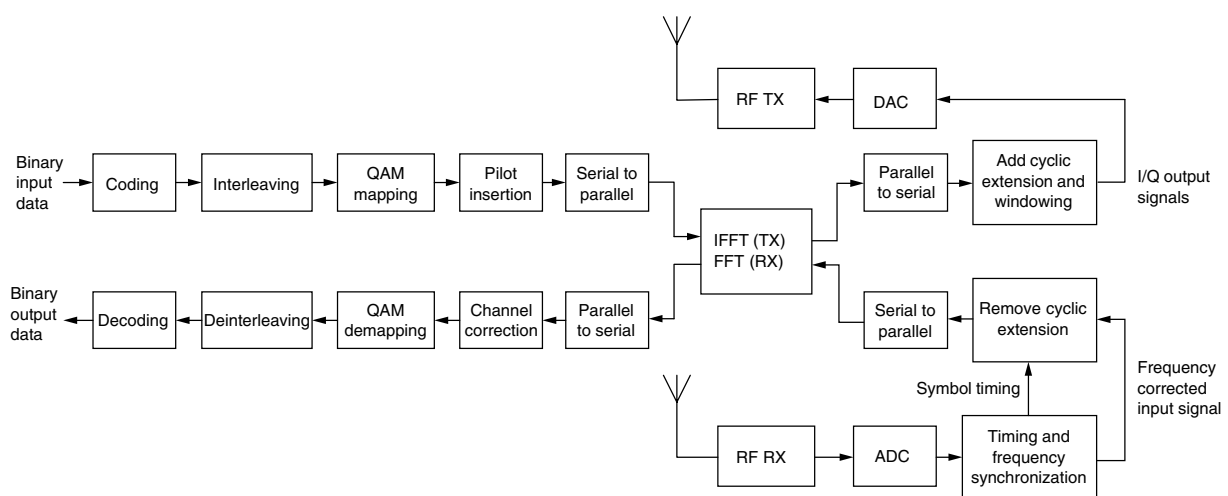

Figure 4. Block diagram of OFDM transceiver.

Figure 5. Time–frequency structure of an OFDM packet. Gray-shaded subcarriers contain known training values.

achieves this by simply allowing IEEE 802.11a OFDM transmissions in the 2.4-GHz band, while 802.11a was originally targeted at the 5-GHz band. To remain coexistent with legacy 802.11b devices, the 802.11 RTS-CTS mechanism can be used to claim airtime for high-rate OFDM packets. If no legacy devices are present in a network, it is possible to transmit 802.11a packets without the RTS-CTS mechanism to maximize user throughput. The IEEE 802.11g standard also defines two optional modulation schemes. The first is CCK-OFDM, where each OFDM packet is preceded by an 802.11b header to provide full coexistence with legacy 802.11b devices without the need for RTS-CTS. The second option is *packet binary convolutional coding* (PBCC), which provides a 22-Mbps raw data rate using coded 8-PSK together with a standard 802.11b header.

With the advent of IEEE802.11g, OFDM has become the single solution for high data rates in both the 2.4- and 5-GHz bands, thereby facilitating the production of dual-band devices. While OFDM is ideal for high data rates, it is expected that the old 1- and 2-Mbps 802.11 rates in the 2.4-GHz band will remain important for providing the largest possible coverage range.

BIOGRAPHY

Richard van Nee before his employment as director of WLAN Product Engineering at Woodside Networks, Dr. Van Nee was a key member of the technical staff at Lucent Technologies/Bell Labs in the Netherlands. Dr. Van Nee was among those who proposed the OFDM-based physical layer, which was selected for standardization

in IEEE 802.11, MMAC, and ETSI HiperLAN. He was involved in the design of the OFDM modems for the European Magic WAND project. Together with NTT, he made the original OFDM-based proposal that lead to the IEEE 802.11a wireless LAN high-rate extension for the 5 GHz band, with data rates up to 54 Mbps. He also was one of the original proposers of the 11 Mbps IEEE 802.11b extension for the 2.4 GHz band, which is based on Complementary Code Keying as described in one of his papers from 1996. Together with Prof. Ramjee Prasad from Aalborg University, Denmark, he wrote the book *OFDM for Mobile Multimedia Communications*, which is a well-read reference for anyone involved with the new IEEE 802.11a standard. He received his Ph.D. in electrical engineering from Delft University, and his M.Sc. in electrical engineering from Twente University.

WIRELESS LOCAL LOOP STANDARDS AND SYSTEMS

HOMAYOUN HASHEMI
Sharif University of Technology
Teheran, Iran

1. INTRODUCTION

Communication plays a vital role in economic development of nations, and in prosperity and well-being of their citizens. A communication plant consists of three main segments: (1) local access plant, the "last mile" of communication, where a subscriber (home or office) is connected to the telephone company's central office; (2) switching facilities, the mechanism that switches and routes calls to their final destination; and (3) long-distance transmission lines, through which calls are transferred within remote areas of the same nation, or between different countries. Segments 2 and 3 have undergone drastic changes in the >125-year history of telephony. The manual switches of early era were transformed into the more advanced electromechanical switches, which then evolved to today's high-speed electronic (digital) switches. "Long distance" lines of 100 years ago consisted primarily of copper wires installed on tens of thousands of telephone poles between cities. Today, millions of calls are transferred nationally and internationally every day by vast and complicated interconnection of high-capacity microwave lines, fiberoptic networks, and low- and high-orbit satellites. The local access technology, however,

remains fundamentally unchanged since the times of Alexander Graham Bell. The dominant local loop up to the mid 1990s was a twisted pair of copper line buried underground to connect the home to the nearest telephone exchange.

Telecommunication systems have gone through three phases of evolution [1]. In the era of interconnection (1876-1950) homes and businesses across cities were wired up to telephone central offices (COs), and COs within a city were connected by wire. Limited long-distance lines were established between cities and nations, again, dominantly by copper wire. In the era of networks (1950-1990) the core network was transformed by expanding, automating, and expediting the switching, call processing, and transport functions. Explosive growth of telephony in this era was fueled by invention and successful deployment of equipment and systems such as digital computers, digital switches, satellites, fiber optics, Integrated Services Digital Network (ISDN), asynchronous transfer mode (ATM) switches, and the Internet. These inventions revolutionized telecommunications, and drastically changed the way people live and work. Great expansion of long-distance telephony, automatic dialing, and introduction of intelligent networking functions are among the achievements of this era. As an example, only 1% of the "core network" in the United States in 1990 was developed in the first 75 years of "interconnection era." The balance of 99% was developed in the 40 years of "network era" [1].

The invention and rapid deployment of cellular radio systems in the 1980s has paved the way for a new era in telecommunications, the "era of access," which started roughly in 1990. This era is manifested by gradual replacement of the primitive, costly, and difficult to install and maintain wired (copper)-based local loops, to the modern, relatively inexpensive, and easy to install wireless local loops (WLLs). It is anticipated that in the near future the majority of telephone services in the world will be based on wireless access (fixed or mobile). Replacement of wired local loop in a sense removes the bottleneck of communications, paves the way for quick, efficient, and economical introduction of other services such as data and video, in addition to the traditional speech communications, a process that expedites transformation of our society into the Information Age.

Basic principles of WLL, including its technical, economical, and regulatory aspects, are described in the literature [1-6].

2. WLL PRINCIPLES

A wireless access system, which is also known as WLL, fixed cellular radio, fixed wireless access (FWA), radio in the local loop (RLL), is emerging as a modern access method. Basic wireline and wireless access system models are shown in Fig. 1. Inspection of this figure shows that a multiple access radio system replaces the wires in the loop.

WLL systems consist of four basic building blocks: (1) a "radio terminal" or "subscriber station," the visible transceiver device carried by or located near the user; (2) a "radio base station," which provides the "wireless" air interface between the subscriber and the network;

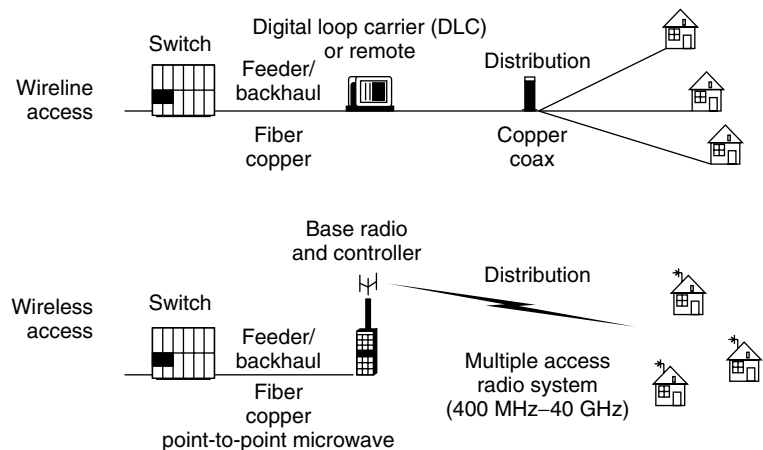

Figure 1. Basic wireline and wireless access system models. (Source: Ref. 2.)

(3) a “network control subsystem,” which controls the wireless access system; and (4) a “fixed network,” the wired infrastructure to which the wireless system provides access.

This scenario can be implemented at each location, independent of other locations, to provide access to limited number of subscribers. The large-scale implementation in an area, however, requires application of spectrum-efficient techniques. Modern WLL is therefore based on principles of cellular radio.

2.1. The Cellular Radio Concept

Cellular radio has been developed for mobile telecommunications, out of a need to increase system capacity and at the same time conserve the scarce radio spectrum. The concept is very simple; a large geographic area is partitioned into smaller local areas called “cells.” The block of radio spectrum (normally consisting of hundreds of channels) is also partitioned into smaller subblocks or “sets.” Channel sets are then assigned to each cell. Two distant cells can use the same channel sets without excessive interference with each other. Repeated reuse of the same channel sets throughout a service area results in drastic increases in system capacity [7]. A mobile subscriber initializes a call while moving in a given cell. When he crosses the cell boundary, calls are “handed off” to the new base station serving the new cell. This process of changing carrier frequency is performed automatically, without any subscriber action.

When telephone traffic in a service area increases, the system capacity can be increased accordingly by “cell splitting,” where new fixed antennas or base stations are placed half-way between existing antennas, splitting large calls into smaller cells. This process increases frequency reuse and therefore system capacity. The cell splitting process is gradual and nonuniform to reflect the nonuniformity of telephone traffic and differences in growth rate throughout a service area.

Cellular radio, originally developed for providing voice communication to mobile (vehicular) subscribers, has evolved since the early 1980s into a sophisticated wireless engine capable of providing variety of services to both fixed and mobile users. Basic principles are described by Lee [8] and Rappaport [9].

2.2. Differences Between Fixed and Mobile Access

Application of cellular radio to WLL is similar to mobile radio, with the exception that in WLL both ends of transmission are normally fixed. This brings a number of advantages [5]:

1. The handoff procedure is not implemented, resulting in simplifications of system design and resource management, and in reduction of system controller’s processing capability requirements. It should be noted that even if the user moves around moderately, this advantage still applies since the coverage area (or cell) does not change.
2. Both antennas are higher, resulting in a line-of-sight link most of the time. Propagation loss is, therefore, smaller, and coverage area is larger.
3. Fixed subscriber transceiver makes higher transmission powers (as compared to mobile) possible.
4. Directional antennas can be implemented at subscriber site, as well as at the base station. This results in higher gain transmission to the desired location, and limited interference to other sites using the same frequency. Smaller overall interference increases frequency reuse and system capacity.
5. Properties 2–4 (above) result in an increase in coverage area. This reduces number of required cells in an area, a great advantage for low-density sparsely populated rural locations where system capacity is not an issue.
6. Unlike mobile access, the nature of traffic is not dynamic. This makes frequency planning easier and more efficient.
7. Stationarity of the subscriber unit results in the absence of short-term multipath fading channel impairments. This results in better quality of service.

In spite of a number of differences between WLL and mobile wireless access, since both are based on the cellular concept, a number of standards originally developed for mobile subscribers have been successfully used for WLL applications.

2.3. WLL Subscriber Base and Types of Service

WLL can provide service to both developed industrial nations, and developing countries.

In developed countries, where a reasonably extensive wireline-based communication infrastructure is in place and telephone penetration is high, WLL can be used to provide cost-effective and easy-to-implement service to low-density remote areas. It can also provide additional low-cost, quick-to-implement service to high-density urban areas.

In developing countries where telephone penetration is normally very low, building a copper-based infrastructure is very expensive and time-consuming. WLL can provide a suitable answer to the basic needs of developing countries by injecting hundreds of thousands of lines into each metropolitan area in a short span of time. Rapid improvements in communication facilities of these countries improve standards of living and reduce economic gaps with developed nations [5]. Cellular radio layout with large cells can also be implemented in remote areas of developing countries to provide single-line service to each village lacking telecommunication privileges. This is the fastest and cheapest method to connect the rural population to the communication network.

It should be noted that communication requirements of developing and developed countries are different. Developing countries mostly need voice telephone lines. Service requirement emphasizes low cost and high capacity, even if voice quality is to be sacrificed. In developed industrial countries emphasis is on quality of service and capability to provide new services. Although WLL principles are the same for both, system design aspects are different [10,11].

Low-capacity WLL systems, not based on cellular, have been used for many decades to provide telecommunication (voice) services to isolated and remote areas of both developed and developing countries. More recently, however, new communication services such as fax, data, and video have grown tremendously. The explosive growth of the Internet technology and services has resulted in an increase in data transmission requirements of modern offices and homes. Such services, a number of which are broadband in nature, have changed telecommunication needs of the subscribers, and have brought new requirements on telecommunication facilities and infrastructure. WLL is also capable of providing these new services. For broadband applications, however, availability of spectrum is an issue. Design concepts are also different.

2.4. Advantages of WLL

Deployment of WLL is gaining momentum for providing service to densely populated urban areas, as well as sparsely-populated remote and rural areas [2–5]. Replacing the wires in the “last mile” of communication with WLL results in the following major advantages:

1. *Speed of Implementation.* Installation of wired local loops involves burial of wires underground, a time-consuming process, especially for longer paths. In WLL, on the other hand, radio units can be installed quickly at both ends of transmission. The speed of implementation within the radio coverage area is insensitive to distance. WLL can be implemented 5–10 times faster than copper-based systems [2].
2. *Small Initial Investment.* Wired local loops require large lumpy investments, as shown in Fig. 2. A

Figure 2. Costs of wireline and wireless access systems versus time. (Source: Ref. 1.)

large initial investment is required to lay down main distribution cables, a capacity that remains unused for long periods of time. Subsequent major expansions also involve other lumps of added investments, which bring no immediate return. WLL, on the other hand, requires investments in small increments to match growth in traffic (Fig. 2). Roughly 20% of installation costs are related to the infrastructure; the remaining 80% is spent at the time when subscriber receives service, which is followed by revenues and immediate return on investment. These advantages make competition feasible for small startup companies with limited capital.

3. *Cheap and Easy Maintenance.* Operational costs of WLL are considerably less than those of wireline loops. One study shows a reduction of 25% per subscriber per year [2]. This study shows that over 30% of trouble reports for wired networks are related to distribution cable, drop wires, and in-home wiring, which all can be eliminated in WLL-based systems. Theft and vandalism of wired loops are other types of loss for telephone companies, which can be avoided by WLL.
4. *Fast and Easy Substitution of Faulty Equipment.* Telecommunication facilities in WLL-based systems are located either at the central office (CO) or in customer premises. In wired loops underground copper wires substitute a major portion of the hardware. Repairs and substitutions in WLL are therefore much faster.
5. *Possibility of Deinstallation and Redeployment.* If subscriber demand in an environment declines, wired loops are simply abandoned, with great capital losses (Fig. 2). In WLL, on the other hand, equipment consisting of radio units at both ends of transmission can be removed and redeployed in other places.
6. *Insensitivity to Subscriber's Exact Location.* Implementation of copper loops requires knowledge of exact subscriber location, in contrast with WLL, in which the subscriber only needs to be within the radio coverage area.
7. *Mobility of Subscriber.* The emphasis of WLL is on providing service to fixed terminals. The radio loop, however, results in the added advantage of subscriber mobility.
8. *Variety of Services.* The twisted pair of copper is a primitive, very-low-capacity transmission medium that has been used traditionally for single-channel voice communication. Effective line capacity of wired loops has been increased by introducing sophisticated (and relatively expensive) digital subscriber loop (DSL) modems at both ends of the loop. Still, the wired loop provides a bottleneck for delivery of broadband video and high bit rate data to subscribers. In radio loops, however, such broadband services can be offered by deploying line-of-sight (LoS) transmission at higher frequencies. Availability of spectrum is, of course, an issue in WLL.

3. WLL TECHNOLOGY

Since large-scale deployment of WLL is based on cellular radio, most techniques and technologies developed for mobile radio applications can be successfully applied to WLL.

3.1. Access Methods

Three major channel access methods for cellular wireless communications are frequency-division multiple access (FDMA), time-division multiple access (TDMA), and code-division multiple access (CDMA) [8,9].

Under an FDMA scheme the allocated band is divided into a number of distinct channels, each one to be used as a single-voice channel. Signals are therefore separate in frequency but mixed in time. In FDMA, when all channels in a cell are occupied, a new call is blocked. FDMA with frequency modulated voice was applied successfully to large-scale mobile telephony in the 1980s. Typically 500–1000 narrowband duplex channels were allocated to a system.

In TDMA, which should better be labeled FDMA/TDMA, the allocated band is first divided into a number of distinct physical channels. Unlike FDMA, however, each physical channel is now used for time multiplexing of several messages. Each user is assigned one of a number of nonoverlapping time slots during which he/she can send or receive digitized messages. Signals are therefore separate in time but mixed in frequency. Transmitter and receiver should have precise time synchronization to avoid inter-channel crosstalk. A number of mobile cellular standards operating on the FDMA/TDMA principle were developed in the 1980s and implemented in the 1990s.

CDMA is a spread-spectrum technique, and therefore benefits from associated antinoise, antiinterference capabilities. In CDMA signals are mixed both in time and frequency. Each user in a cell is assigned a distinct code that has a large bandwidth. Codes have good orthogonal properties. At the receiver a correlator is used to correlate the received signal with a replica of the transmitted code (for that particular user). The original message is therefore reconstructed. One great advantage of CDMA is its high capacity. In cellular CDMA, which is also FDMA/CDMA in nature, every physical channel is assigned to each cell. This process eliminates the need for frequency planning, in addition to increasing capacity. CDMA enjoys a "soft capacity limit," in which an additional user can always be accommodated at the expense of small added interference to all other users in the same cell. Successful implementation of CDMA requires accurate synchronization and appropriate power control capabilities. Performance and capacity of CDMA for mobile radio applications were subjects of intense debate in the 1990s. Only one major mobile radio standard based on CDMA emerged in the 1990s. More recently developed wireless communication standards are, however, based mostly on CDMA technology.

TDMA and CDMA can each be either narrowband or wideband. This refers to the width of each physical channel. Wideband schemes have higher capacities and are capable of accommodating new high-bit-rate

nonvoice services. Implementation, however, is more difficult. Newly emerging wireless standards are wideband-oriented.

WLL systems can operate in both frequency-division duplex (FDD) and time-division duplex (TDD) modes. In FDD a pair of duplex channels, widely separated in frequency, are assigned to a user for two-way transmission. In TDD the same physical channel is used for both downlink (base-to-subscriber) and uplink (subscriber-to-base) transmissions. Each subscriber using the physical channel, however, sends and receives messages at different time slots. With exceptions, most currently working wireless systems operate on FDD mode. The emerging systems use both FDD and TDD.

3.2. Resource Management

Successful deployment of large-scale WLL systems depends on efficient use of scarce radio spectrum, which in turn requires good channel assignment policies. There are two major techniques: fixed channel assignment (FCA), and dynamic channel assignment (DCA). Each technique contains a number of variations, and a combination of the two has also been suggested.

In FCA the available channels are partitioned into blocks or "sets." During initial planning of the system, channel sets are assigned to each cell according to forecast traffic requirements. Although initial planning of FCA is sophisticated and requires knowledge of traffic distributions throughout the service area, its later operation is relatively simple. The great disadvantage of FCA is its lower capacity (compared to that of DCA). This is particularly true where traffic distribution is nonuniform.

In DCA all channels are assigned to every cell. Channel assignment for each call is performed by a central processor on an individual basis, after taking interference limitation requirements of the system into account. The advantage of DCA is minimal initial planning and high capacity, especially where traffic distribution is nonuniform in space, and changing with time. The major disadvantage of DCA is elaborate call supervision, which puts a heavy burden on the central processor for small-cell high-capacity systems. With exceptions, current mobile wireless systems use FCA. The emerging standards, however, take advantage mostly of DCA.

All currently available wireless (fixed or mobile) systems are based on circuit switching, where a dedicated circuit is allocated to a user throughout the connection. The circuit may be an FDMA channel, a time slot of a TDMA channel, or a CDMA orthogonal code. On termination of the call the circuit is marked "idle," and later assigned to a new user. The newly emerging standards operate on both circuit-switching and packet-switching modes. In packet switching there is no permanent connection for a user. A number of calls are made using the same channel. This channel is assigned to a number of users on a temporary basis. Each user sends its information in "packets" at assigned intervals. This scheme increases efficiency, and hence capacity, but requires great call supervision and sophisticated processing. Although packet switching can be used for speech, it is more suitable for data transmission applications, which are bursty in nature.

4. WLL STANDARDS

In principle any wireless personal communication standard can be used for WLL systems. The standards, however, are grouped in two major categories: standards based on existing and emerging digital mobile radio systems, and those based on proprietary radio technologies. The first category covers open standards developed by recognized standardization bodies. They provide network operators with the freedom of supplying different subsystems from different manufacturers. In the second category the entire system is normally developed by a specific manufacturer based on proprietary-developed standards.

4.1. Mobile-Radio-Based Standards

Wireless mobile communication is the fastest-growing sector of the telecommunications industry, providing service to over one billion customers worldwide. The exponential growth in number of subscribers started in early 1980s with commercial introduction of systems based on the cellular radio principles.

Wireless cellular communications has undergone three distinct phases of expansion, known as first, second, and third generations:

First-generation (1G) systems, designed in the 1970s, and commercially introduced in early 1980s, are based on single-channel analog FM technology with channel spacings of 25 or 30 kHz. Such systems, which are still operating in parts of the world, are used almost exclusively for duplex voice transmissions.

Second-generation (2G) systems were designed primarily in 1980s and commercially deployed in 1990s. They are all based on digital technology, making compact and power-efficient transceivers feasible. The primarily vehicular-mounted units of the first generation were, therefore, transformed into personal portable units of the second generation. Low-bit-rate data communication services are also introduced in 2G.

Third-generation (3G) systems also operate on digital technology principles. Higher bandwidths allocated to 3G, combined with more sophisticated signal processing techniques, have greatly improved capacity and capabilities of wireless services. 3G is the gateway to personal multimedia, in which standards are capable of providing speech, data, video, and Internet services to wireless (mobile or fixed) units. International coordination for standardization of 3G has been performed by the ITU (International Telecommunications Union) in the framework of IMT-2000 (International Mobile Telecommunications) plan. Implementation of 3G systems started in 2002.

4.1.1. Major Second-Generation Standards. Major second-generation mobile radio standards that are also candidates for WLL are GSM, IS136, IS95 (high-power systems, originally developed for providing service to high-speed vehicular subscribers moving in outdoor large cell

environments), and DECT, PACS, and PHS (low-power microcellular systems, originally intended to provide coverage to low-speed outdoor pedestrians, and indoor users) [2]. Second-generation standards are reviewed by Black [12].

Detailed evaluations of DECT, PACS, and PHS standards have shown the suitability of all three for WLL applications [6]. Basic parameters of second generation standards are summarized below.

4.1.1.1. GSM (Global System for Mobile Communication). GSM, developed by CEPT (Conference Europeenne des Postes et Telecommunications) in the 1980s to serve as a pan-European unified standard, evolved into a "model" digital mobile communications standard with the largest subscriber base in the world. GSM was standardized by ETSI (European Telecommunications Standard Institute). It operated in the FDD mode with 25 MHz bandwidth (935–960 MHz for downlink, and 890–915 MHz for uplink). Each band consists of 125 physical channels, each 200 kHz wide. Every physical channel operates in the TDMA mode with 8 user channels, each 0.577 ms. wide, forming 4.615-ms-long frames. Speech coding is RPE-LTP (regular pulse excited–long-term prediction) with 13 kbps (kilobits per second) for each subscriber. A combination of CRC and rate- $\frac{1}{2}$ convolution channel coding results in a gross bit rate per channel of 22.8 kbps. Modulation is Gaussian minimum shift keying (GMSK). GSM channel assignment is fixed (FCA).

The success of original GSM standard, and insufficiency of the original 900-MHz band resulted in introduction of DCS-1800 (Digital Communication System). This standard occupies a duplex pair of bands, each 75 MHz wide (1710–1785 MHz uplink, 1805–1880 MHz downlink). Each band, therefore, accommodates 375 channels with channel spacing of 200 kHz. All other parameters of DCS-1800 are identical to those of GSM. More details on GSM standard can be found in studies by Black [12] and Mehrotra [13].

4.1.1.2. North American TDMA Digital Cellular (IS136). The TDMA-based IS136 standard was developed by TR45.3, a subcommittee of the EIA/TIA (Electronic Industry Association/Telecommunications Industry Association) in the United States. IS136 is compatible with the analog, first-generation system AMPS (advance mobile phone service). It operates in two frequency bands (869–894 MHz uplink, 824–849 MHz downlink). There are 832 physical channels with a channel spacing of 30 kHz (the same as analog FM channels used in AMPS). Channel assignment is FCA. Each channel accommodates three users in TDMA mode with a channel bit rate of 48.6 kbps. TDMA frame length is 40 ms, speech coding is VSELP (vector sum excited linear predictive), channel coding is rate- $\frac{1}{2}$ convolution, and modulation is $\pi/4$ -DQPSK (differential quadrature phase shift keying). The standard provides flexibility to accommodate six users in the same 30-kHz band. Black has reported the details of this standard [12].

4.1.1.3. North American CDMA Digital Cellular Cdma-One (IS95). This is the first CDMA digital cellular

standard in the world, developed by Qualcomm Inc. in the United States, and standardized by Subcommittee TR45.5 of the EIA/TIA in 1993. The standard uses the same 800-MHz band as analog AMPS and digital TDMA IS136 standards. Each duplex band of 25 MHz is, however, divided into 20 channels, each 1.25 MHz wide. Each channel provides service to a number of users, which are each assigned a distinct code. The technique is based on direct-sequence spread spectrum in which the 9.6-kbps user data are converted to 1.2288 Mcps (million chips per second), occupying one 1.25-MHz physical channel. Frame length is 20 ms, speech coding is QCELP (Qualcomm code excited linear predictive), channel coding is rate- $\frac{1}{2}$ convolution in the downlink/uplink paths, and modulation is OQPSK (offset QPSK). Channel assignment of IS95 is DCA. More details of the standard are reported by Black [12].

4.1.1.4. DECT (Digital Enhanced Cordless Telecommunications). DECT is a European standard also developed by ETSI. It is designed to operate in the 1880–1900-MHz frequency band, with flexibility to use other close bands. It is based on the TDMA-TDD principle. The number of carriers is 10, and carrier separation is 1726 kHz. The transmission rate is 1152 kbps, and the number of TDMA channels for each carrier is 12. Therefore, the total number of voice channels is 120 (10 carriers \times 12 time slots per carrier). Speech coding is 32 kbps ADPCM (adaptive differential pulse code modulation), and modulation method is GFSK (Gaussian frequency shift keying). Channel assignment is dynamic. Maximum transmission power of the base and portable is 250 mW, where dynamic power control reduces it down to 60 mW. This, however, is peak power used during the transmission of a time slot. Average power is ≤ 10 mW, resulting in long battery usage before recharge. Normal cell radius in DECT is several hundred meters. For each voice connection two time slots are used for two-way transmission. In the other 22 time slots the portable unit scans and evaluates other channels for handover to a better channel when available. More information about DECT can be found in the article by Yu et al. [14].

4.1.1.5. PACS (Personal Access Communication System). PACS has been developed in the United States and was standardized by the JTC (Joint Technical Committee) in 1994. It operates in two wide duplex bands 1850–1910 MHz (uplink) and 1930–1990 MHz (downlink). These bands were allocated by the FCC (Federal Communications Commission) in three paired 5-MHz and three paired 15-MHz bands for licensed wideband PCS applications. Also a 10-MHz band (1920–1930 MHz) has been allocated for unlicensed TDD operation. The air interface of PACS allows FDD operation in the licensed band and TDD operation in the unlicensed band [15].

The PACS standard is based on FDD-TDMA (frequency-division duplex) with 200 channels (carrier separation of 300 kHz). Modulation and speech coding are $\pi/4$ -QPSK (quadrature phase shift keying) and 32 kbps ADPCM (adaptive pulse code modulation), respectively. Bit rate per channel is 384 kbps.

Table 1. Basic Parameters of the Second-Generation Wireless Standards

System	High-Power Macrocellular			Low-Power Microcellular		
	GSM	IS136	IS95	DECT	PACS	PHS
Frequency band (MHz)	935–960 890–915	869–894 824–849	869–894 824–849	1880–1900	1850–1910 1930–1990	1895–1918
Standardization body	ETSI	EIA/TIA TR45.3	EIA/TIA TR45.5	ETSI	JTC	ARIB
Duplex method	FDD	FDD	FDD	TDD	FDD	TDD
Access method	FDMA/TDMA	FDMA/TDMA	FDMA/CDMA	FDMA/TDMA	FDMA/TDMA	FDMA/TDMA
Number of carriers	124	832	20	10	200	77
Carrier separation (kHz)	200	30	1250	1728	300	300
Modulation	GMSK	$\pi/4$ -DQPSK	QPSK	GFSK	$\pi/4$ -QPSK	$\pi/4$ -QPSK
Rate per channel (kbps)	270.83	48.6	1228.8	1152	384	384
Frame time (ms)	4.615	40	20	5 + 5	2.5	2.5 + 2.5
Slots per frame	8/16	3/6	1	12 + 12	8	4 + 4
Speech coding type and rate (kbps)	RPE-LTP, 13	VSELP, 7.95	QCELP, 9.6	ADPCM, 32	ADPCM, 32	ADPCM, 32
Channel coding	Rate- $\frac{1}{2}$ convolution	Rate- $\frac{1}{2}$ convolution	$\frac{1}{2}$ forward $\frac{1}{3}$ reverse	CRC	CRC	CRC
Channel assignment	FCA	FCA	DCA	DCA	QSAFA	DCA
Modulation efficiency (bps/Hz)	1.35	1.62	0.98	0.67	1.28	1.28
Handoff strategy	Mobile-assisted	Mobile-assisted	Mobile-assisted	Mobile-controlled	Mobile-controlled	Mobile-assisted

Channel assignment is quasistatic autonomous frequency assignment (QSAFA/DCA) [15]. The standard is designed for low mobility applications. However, operation at high speed (several tens of kilometers per hour) is also possible. Maximum transmission power of the portable unit is 200 mW, and average power is 25 mW. More details about PACS have been reported [14,15].

4.1.1.6. PHS (Personal Handy-Phone System). PHS is the Japanese-developed standard operating in the 1895–1918-MHz band. PHS was envisioned as an efficient low-cost cordless and portable phone system. In late 1993 RCR (Research and development Center for Radio systems), currently known as ARIB (Association of Radio Industries and Businesses), approved the RCR STD-28 standard. The interface for connection to the network was subsequently completed by the TTC (Telecommunication Technology Committee), and trial systems started operation. The first commercial system was implemented in mid-1995. Since then, PHS has experienced explosive growth in Japan, reaching a market size of over 8 million in 1999.

PHS is based on the TDMA-TDD principle with 77 channels (carrier separation of 300 kHz). Bit rate is also 384 kbps, and modulation is $\pi/4$ -QPSK. Speech coding is 32 kbps ADPCM and channel assignment is dynamic. Each physical channel can be used as four traffic

channels in the TDMA mode. Details of PHS are reported in Ref. 16.

Table 1 summarizes parameters of the six major high-power and low-power second-generation digital cellular standards.

4.1.2. Major Third-Generation Standards. The unparalleled success and exponential growth in first-generation mobile communication systems in the early 1980s necessitated initiation of collective efforts in developing standards that could be used internationally to realize the slogan of PCS (personal communication services), wireless access of “any kind, to any one, and at any where.” Such efforts were initiated at the ITU in 1985 in the framework of FPLMTS (future public land mobile telephone systems), which was later renamed IMT-2000. The goals set at IMT-2000 was to provide flexible and spectrum efficient voice and data services to wireless users. The minimum bit rate requirements for outdoor high-speed macrocellular, outdoor pedestrian microcellular, and indoor picocellular environments are 144 kbps, 384 kbps, and 2 Mbps, respectively.

To satisfy the needs of a large international subscriber base requires two-way transmission of low-to-high bit rate data and video in addition to conventional voice telephony. The ITU allocated 230 MHz in the 2 GHz band at WARC’92 (World Administrative Radio Conference). The frequency bands are 1885–2025 MHz and

2110–2200 MHz. To provide global coverage and roaming capabilities, both terrestrial and satellite links were considered.

Many proposals were submitted to the ITU, and a number of standards capable of fulfilling the IMT-2000 vision emerged in the late 1990s. The three major standards, two of them based on wideband CDMA, and one on wideband TDMA, are described in this section. The degree of suitability of each standard for WLL applications is yet to be determined. However, the anticipated large-scale deployment of equipment based on these standards, which results in introduction of economically attractive systems, coupled with the capability to provide new higher bit rate services, make these standards suitable candidates for future WLL systems.

Major third-generation standards have been described [17,18].

4.1.2.1. European-Based WCDMA (Wideband CDMA).

This standard, which is also supported by the Japanese wireless industry, has been developed by ETSI in the framework of the European UMTS (Universal Mobile Telecommunication Systems) project. UMTS is the European version of IMT-2000. WCDMA operates in the paired band of the IMT-2000 spectrum based on FDD. It uses 5-, 10-, 15-, and 20-MHz-wide channels, and operates at chip rates of 1.024, 4.096, 8.192, and 16.384 Mcps. Frame length is 10 ms. Provisions are made for multirate and packet data services. The standard is backward-compatible with GSM. Yang has described the basic principles and applications of CDMA [19]. Detailed descriptions of WCDMA are provided by other authors [20,21].

4.1.2.2. North American WCDMA Standard Cdma2000.

The cdma2000 standard was finalized by the Subcommittee TR45.5 of the TIA Engineering Committee TR45 in the

United States in March 1998. It is backward-compatible with the cdmaOne (IS95) standard. Provisions for packet data transmission are provided, channel bandwidths are $N \times 1.25$ MHz ($N = 1, 4, 8, 12, 16$), and chip rates are 1.2288, 3.6864, 7.3728, 11.0593, and 14.7456 Mcps. Frame length is 20 ms.

4.1.2.3. North American UWC-136 (Universal Wireless Communications). The UWC-136 standard, prepared by Subcommittee TR45.3 of the TIA, is a family of technologies based on TDMA. It consists of (1) the IS136 standard with 30-kHz channels for speech and data below 28.8 kbps; (2) IS136+, which again uses 30-kHz channels for speech and data (bit rates, however, are increased to 64 kbps applying M -ary modulation; (3) IS136 HS (high speed) for outdoor vehicular applications using 200 kHz wide channels (data rates of ≤ 384 kbps are possible; duplex policy is FDD); and (4) IS136 HS indoor, in which the 1.6-MHz-wide channels make data rates up to 2 Mbps feasible. FDD and TDD methods are both used. IS136 HS is also compatible with GSM, using the same frame length of 4.615 ms.

The basic parameters of major 3G standards are summarized in Table 2. Further details can be found in the literature [17,18].

4.2. Proprietary Radio Interface Standards

These standards are developed by private organizations to replace the existing wired loops. Such standards cover a wide range of carrier frequencies, radio interface technology, transmission rates, range, performance, and types of service. Major standards cited by the ITU are Nortel Proximity I-Series, SR Telecom's SR 500, and TRT/Lucent Technologies IRT [2]. Other major systems cited by Webb [3] are Innwave Multigain, Airspan, Lucent AirLoop, Interdigital Broadband CDMA, and Granger CD2000. An overview of these standards and

Table 2. Basic Parameters of the Third-Generation Wireless Standards

System	WCDMA	Cdma2000	UWC-136		
			IS136+	IS136 HS Outdoor/Vehicular	IS136HS Indoor
Backward compatibility	GSM	CdmaOne (IS95)		IS136	
Standardization body	ETSI	EIA/TIA TR45.5		EIA/TIA TR45.3	
Access method	WCDMA	WCDMA		TDMA	
Carrier separation	5, 10, 20 MHz	1.25, 5, 10, 15, 20 MHz	30 kHz	200 kHz	1.6 MHz
Maximum user bit rate per code or channel	480, 960, 1920 Kbps	1.0368 Mbps	64 Kbps	384 Kbps	2 Mbps
Maximum user bit rate (multicode)	2 Mbps	2 Mbps		N/A	
Chip rate (Mcps)	1.024, 4.096, 8.192, 16.384	1.2288, 3.6864, 7.3728, 11.0593 direct spread $n \times 1.2288$ ($n = 1, 3, 6, 9, 12$) for multicarrier		N/A	
Frame length (ms)	10	20	40	4.615	4.615

details of their basic parameters have been presented by the ITU [2] and Webb [3].

5. WLL SPECTRUM AND CAPACITY

Large-scale deployment of WLL depends on availability and efficient use of the radio spectrum. Wireless access systems, fixed and mobile, operate in the wide frequency range of 400 MHz–40 GHz. A number of analog FM systems based on European standards operate at 400 MHz. IS136 mobile cellular uses the 800-MHz band, while GSM operates at 900 MHz. Point-to-multipoint radio in the loop has been designed at 1.4 GHz. The 1.8–1.9-GHz bands are used for GSM, DECT, and PHS standards. A wide band at 2 GHz has been allocated by the ITU for global implementation of IMT-2000 standards. Multipoint distribution systems (MDSs) and point-to-multipoint radio also operate at 2.4, 2.5, 2.6, and 10.5 GHz. Finally, 28- and 40-GHz bands are used for local multipoint communications and distribution systems (LMCS/LMDS) [2]. Most of these frequencies, especially lower bands, have been developed for mobile users; however, they are either being used, or have the potential of being used for WLL-type applications.

Capacity is the most critical issue in wireless personal communications, fixed or mobile. Cellular radio architecture provides high capacities because of its spectrum efficiencies [22]. It has been shown by an example that even the relatively low capacity cellular analog FM standards are capable of providing millions of fixed WLL-type telephone lines in a metropolitan area if a reasonably large frequency band is allocated [5]. Capacity of digital cellular systems is higher than analog because (1) speech coding reduces bandwidth per subscriber, and (2) channel coding results in smaller signal-to-interference requirements, which in turn decreases minimum reuse distance, and further increases capacity.

Performance and capacity of DECT, PACS, and PHS standards for WLL applications have been reported [6]. Detailed qualitative and quantitative evaluations indicate that all three standards provide satisfactory performance for WLL applications. For low-traffic environments, PACS which can employ larger cells performs better than the other two standards. In suburban areas where in addition to coverage capabilities capacity is an issue, DECT has better performance. For high-traffic-density urban areas with great capacity requirements, the three standards all have good performance [6].

TDMA systems have higher capacity than do FDMA systems. In CDMA more interference can be tolerated, which boosts capacity even higher. The CDMA-versus-TDMA capacity of cellular mobile radio systems was a subject of intense debate in the 1990s. Real capacity evaluations are difficult due to a large number of parameters and assumptions. It has been suggested [3] that capacity of CDMA for WLL applications is 1.4–2.5 times that of TDMA. Cell sectorization results in even further CDMA capacity improvements.

Capacities of cellular mobile and fixed WLL have been compared with reference to detailed calculations [10,11]. In one study, the capacities of the IS136 (TDMA), GSM

(TDMA), and IS95 (CDMA) standards were evaluated in detail and compared for both fixed and mobile access [10]. CDMA WLL capacity (measured in erlangs per cell per MHz) was found to be about 2.5 times that of IS136, and about 5.4 times that of GSM. Detailed analysis [11] has shown that capacity of WLL is not necessarily higher than that of mobile if FDMA or TDMA is used. It is higher if CDMA is applied. For WLL applications alone, CDMA always provides higher capacity than does TDMA [11].

Many advantages of CDMA have made it the major access method for the emerging third-generation wireless mobile standards. CDMA is also expected to be access of the choice for WLL applications in years to come.

6. ECONOMICS OF WLL

Successful deployment and operation of any communication system depends on its economic viability. In a typical system the operator makes an initial capital investment to build the initial infrastructure for a system that will grow and provide service to a large number of subscribers in the future. Interest should be paid on the capital sum until the network becomes profitable. Revenues increase as customer base increases. There are also ongoing maintenance, upgrade, and marketing costs associated with operation of the system.

A typical communication system consists of a core network of switching and transmission equipment for backhaul connections, and the access part, which connects the subscriber to the network. The network cost is approximately the same for wired and wireless loops. The per subscriber cost of the core network, estimated at \$30–\$60 for a large network of half a million users [3], is insignificant as compared to the cost of access. Detailed cost evaluations are complex for both wired and wireless access (especially wired) because of the large number of interrelated parameters. It is also changing with time as a result of inflation and changes in technology. However, one can compare the two by elaborating on the involved parameters of each, and by looking at their trends.

6.1. Cost of Wired Loops

The copper-based wired loops require lumps of investments to lay down main cables to support a future large subscriber base. The cost of unused capacity and the interest payments on the initial large capital makes competition stiff for small-size new operators. The cost per line of the access varies greatly, depending on the number of customers, length of loop, and type of terrain. As an example, analysis of cable costs for 30 rural area sites in the United States in 1990 showed a per line cost as low as \$834 and as high as \$50,000. The average per line cost for all 30 sites covering 8282 subscribers was \$3102 [1]. Looking at the trends, however, it can be shown that cost per access line increases almost linearly as a function of length of access line, up to a point where it takes a jump as a result of required loading coils. From that point it increases almost linearly, although with a larger slope due to the required shift to larger gauge cable. Increasing the distance results in another jump for insertion of additional loading coils,

and a subsequent exponential increase afterward due to even larger gauge cable, and due to the fact that very long loops normally involve higher costs because of difficult terrain [1].

The per line cost of wired loops in a flat area normally decreases as penetration (subscriber density) increases. Simple calculations by Webb [3] indicate that in an environment where houses are located adjacent to each other, cost per subscriber increases from \$450 to \$1650 when penetration decreases from 100% to 20%.

6.2. Cost of Wireless Loops

In wireless local loops, investments are made in small increments, matching growth in traffic (Fig. 2). The large idle initial investment can, therefore, be avoided. Subsequent interest payment on investment is also considerably smaller. Installation costs are divided typically 20% on infrastructure (initial investment for base station equipment) and 80% on subscriber (paid when the customer receives service, which is immediately followed by generated revenue). These factors make WLL particularly attractive for low-capital new-entrant operators.

The cost of wireless access also depends on a number of factors, including type of access and subscriber density. Per subscriber costs are lowest for low-power microcellular systems operating in dense outdoor urban areas and in indoor environments. The cost is highest for megacellular satellite systems providing coverage to low-density rural areas. The most important aspect of WLL cost is that it is distance-insensitive. If a subscriber is within the coverage area of a base station, its distance to the base does not affect cost.

The cost of WLL can be divided into “shared” and “dedicated.” Shared costs are those allocated to a number of subscribers, such as base station equipment. Dedicated

costs are per subscriber costs such as terminal transceiver and antenna. Calhoun [1] subdivided WLL costs into the following five major categories:

1. *Common equipment costs*, such as power supplies, base station antennas, and central processor for system control. This type of cost does not vary with the size of the system.
2. *Traffic-sensitive equipment costs*—costs mainly for RF channel hardware (base station transceiver or radio units), the cost of which depends on the number of subscribers and average traffic statistics.
3. *Per subscriber equipment costs*—costs related to equipment purchased one unit per subscriber. This includes subscriber transceiver, and line card to interface the central office.
4. *Ancillary materials and labor*—includes costs for the pole, antenna, and power supply, all installed in customer premises, and dedicated to a single customer, or shared by a number of customers at the same location.
5. *Overhead charges*—costs charged as a standard percentage of the total value of a project.

This cost structure is depicted in Fig. 3. A simple but effective formula to estimate cost of wireless loops is also provided by Calhoun [1]. The total project cost R is given by $R = AX + BY + C$, where X is the number of subscribers and Y is the number of radio channels. A , B , and C are equipment cost of the per subscriber equipment (item 3 above), equipment cost of per RF-channel equipment (item 2), and cost of the common equipment (item 1), respectively. The relationship between X and Y is not fixed; it depends on the user calling habits (average holding times) and on the grade of service (blocking probability).

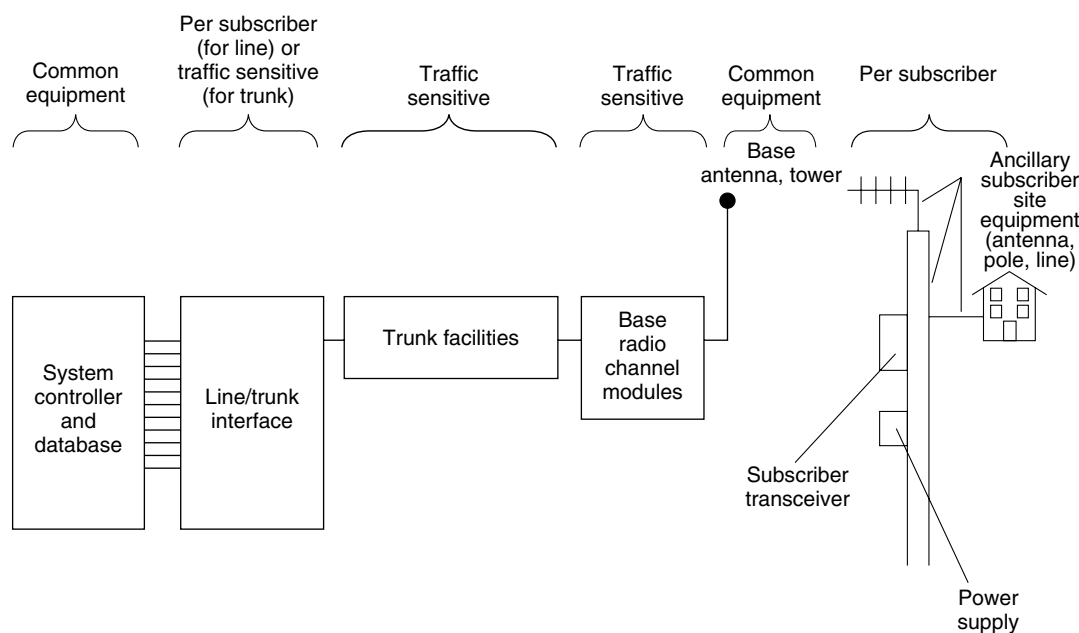

Figure 3. Major components of WLL for cost categorization. (Source: Ref. 1.)

Using this approach, one can deduce that total per subscriber cost is high for small X ; it decreases rapidly as X increases, and reaches a lower limit (saturation point) where cost of subscriber station plus traffic-sensitive base station cost are dominant cost factors.

6.3. Comparison Between Wired and Wireless Costs

The costs of wired and wireless loops are both decreasing functions of subscriber density (number of subscribers per square kilometer). Comparison of wireless and wireline systems in terms of capital (installation) cost is provided in Fig. 4. Cost per subscriber of WLL in the 1990s was lower than in the 1980s because of mass production of cellular equipment and the "negative inflation" phenomena associated with electronics. Figure 4 shows a breakpoint around 100 subscribers per square kilometer. As time passes, this breakpoint is expected to shift even further to the right (i.e., WLL becomes economically superior for even larger subscriber densities). The reason is that wired loop economy depends on the cost of raw material (copper) and labor, both of which increase with time. WLL economy on the other hand, is governed by the "negative inflation" phenomena associated with electronics.

A case study comparing economy of two access methods is provided by Webb [3]. Three flat areas representing a range of housing densities (high-density, medium-density, and low-density) were considered. It has been shown that in each case when penetration (fraction of houses subscribing to the service) decreases from 25% to 10%, cost per subscriber of cable access increases almost linearly with a modest slope. When penetration decreases below 10%, slope of the cost curve rises sharply. The cost of WLL, however, remains almost the same for penetrations of 5–25%. This comparative study also indicates that per subscriber cost of wired loops is much more sensitive to housing density, as compared to the cost of wireless loops.

Another study shows that a combination of wired and wireless loops provides best economic solutions for

a number of cases [1]. In this study relative cost is plotted as a function of percentage of wireless loops, ranging from 0 to 100%. There is an optimum percentage point where the cost is lowest. The optimum point, however, is very sensitive to the individual case, and to the governing parameters and assumptions. It is important to note that capital (installation) cost is only one aspect of economic feasibility. A valid comparison of the two access methods should be based on "annual lifetime cost," which contains capital cost, operating cost, and replacement cost. Such analysis points further at the superiority of WLL [2]. It is estimated that up to 80% of a telephone company's total maintenance cost is allocated to the local loop. WLL represents great savings in maintenance costs since the expensive operations associated with digging the ground and replacing wires are totally eliminated. Operating expenses can be reduced by as much as 25% per subscriber per year in WLL [2]. Considering lifetime cost per subscriber instead of installation costs alone makes WLL superior to wireline-based networks for subscriber densities below approximately 200–400 subscribers per square kilometer. The exact position of the crossover point depends on specific assumptions, distribution of subscribers, and traffic levels.

A major conclusion is that "Wireless access based systems are cost-effective for the provision of telephony services to typical residential subscribers, particularly in rural and suburban areas, or for new entrants in competitive urban markets" [2]. Economic feasibility, combined with other advantages described before, makes WLL access the access of choice in most cases. Large-scale deployment, however, is subject to availability of radio spectrum.

7. BROADBAND APPLICATIONS OF WLL

For over 100 years telecommunication systems have been dominated by "telephony," that is, two-way transmission of voice. More recently, however, delivery of broadband services such as high-speed Internet and video to the home and office has become increasingly important. Fixed wireline operators are considering digital subscriber techniques such as ADSL (asymmetric digital subscriber line) to increase capacity of copper lines [23]. Very-high-bit-rate services to subscribers can also be delivered by fiberoptic-based techniques such as FTTC (fiber to the curb) and FTTH (fiber to the home). These techniques, however, share many disadvantages with the copper-based local loops.

Subject to allocation of sufficient radio spectrum, WLL is also capable of providing broadband services. It should be noted that "broadband" is not a well-defined term. In voice-oriented mobile telephony, transmission rates above 100 Kbps are considered as "high bit rates." For cable operators, broadband is 8 Mbps or higher.

Technical and economical aspects of broadband WLL, along with a forecast of future are provided by Webb [3]. Third-generation mobile wireless standards provide a peak data rate of 2 Mbps in indoor picocellular environments at the 2-GHz band. This rate provides limited

Figure 4. Cost versus subscriber density for wireline and wireless access systems. (Source: Ref. 2.)

multimedia capabilities. The emerging new broadband services, however, require higher data rates. As an example, in 1997 the ETSI established the BRAN (Broadband Radio Access Network) project in Europe [24]. The purpose of the project was to utilize broadband LAN (local-area network) technology and broadband fixed radio access to provide mechanisms for delivery of multimedia services to subscribers. In the framework of the BRAN project HiperAccess was suggested for WLL systems. The BRAN project came to the conclusion that a peak data rate of 25 Mbps is sufficient for most broadband user-oriented applications (1.5–6 Mbps for video applications, 2 Mbps for Web browsing, 10 Mbps for corporate access, and up to 25 Mbps for LAN connections). Such high bit rates, however, require transmission at much higher frequencies (say, above 10 GHz), for which technology is evolving. Simple calculations [3] have shown that for economic viability of broadband WLL services, assignment of radio spectrum at least 10 times the bandwidth offered to a user is required. A major conclusion is that “for typical assignments in the frequency bands of 10 GHz and above, bandwidths of 10 MHz per subscriber, using WLL would seem readily achievable” [3]. A number of standards for broadband WLL are being developed, and a number of broadband proprietary WLL products are being introduced to the market [3]. It is safe to expect widespread deployment of broadband WLL-based systems and services in the near future.

8. CONCLUSIONS

In this tutorial presentation the basic principles and applications of fixed wireless access, or WLL, were reviewed. WLL technology, standards, spectrum efficiency, capacity, and economics were described.

A major conclusion is that WLL is an efficient and economically feasible alternative for wired local loops. Major second-generation mobile radio standards, as well as proprietary radio interface standards, have been deployed in WLL applications. Third-generation mobile radio standards and emerging broadband WLL standards, mostly based on wideband CDMA, are potential candidates for providing voice and data services to subscribers in high-density urban areas, as well as sparsely populated rural areas.

BIOGRAPHY

Homayoun Hashemi received the B.S.E.E. degree from the University of Texas at Austin in 1972, and the M.S. and Ph.D. degrees in Electrical Engineering and Computer Sciences, and the M.A. degree in Statistics, all from the University of California at Berkeley, in 1974, 1977, and 1977, respectively. He joined Bell Telephone Laboratories, Holmdel, New Jersey in 1977, where he was involved in system design for high-capacity mobile telephone systems. Since 1979 he has been a faculty member at Sharif University of Technology in Teheran, Iran, where he is currently a full Professor of Electrical Engineering. Dr. Hashemi has

done research on different aspects of wireless communications, with emphasis on propagation modeling. His channel simulator package SURP has been used internationally in the design of digital cellular radio communication systems. He spent one year at NovAtel Communications Ltd. in Calgary, Canada in 1990, the summers of 1992 and 1994 at the Electrical Engineering Department of the University of Ottawa, and the summer of 1993 at TRILabs in Calgary. During these visits he defined and supervised three major projects; in each of these projects the largest propagation database of its kind in the world, even to this date, was set up and analyzed. He received the “Best Paper Award” at the IEEE, VTC’99 Conference, and the IEEE Vehicular Technology Society’s Neal Shepherd Best Propagation Paper Awards in 2000 and 2001.

WIRELESS LOCATION

ALI H. SAYED
 NABIL R. YOUSEF
 Adaptive Systems Laboratory
 University of California
 Los Angeles, California

1. DEFINITION

Wireless location refers to obtaining the position information of a mobile subscriber in a cellular environment. Such position information is usually given in terms of geographic coordinates of the mobile subscriber with respect to a reference point. Wireless location is also commonly termed *mobile positioning*, *radiolocation*, and *geolocation*.

2. APPLICATIONS

Wireless location is an important public safety feature of future cellular systems since it can add a number of important services to the capabilities of such systems. Among these services and applications of wireless location are [e.g., 1–11]:

1. *E-911*. A high percentage of emergency 911 (E-911) calls nowadays come from mobile phones [1,2]. However, these wireless E-911 calls do not get the same quality of emergency assistance that fixed-network E-911 calls enjoy. This is due to the unknown location of the wireless E-911 caller. To face this problem, the Federal Communications Commission (FCC) issued an order on July 12, 1996 [1], which required all wireless service providers to report accurate mobile station (MS) location to the E-911 operator at the public safety answering point (PSAP). According to the FCC order, it is mandated that within 5 years from the effective date of the order, October 1, 1996, wireless service providers must convey to the PSAP the location of the MS within 100 m of its actual location for at

least 67% of all wireless E-911 calls.¹ It is also expected that the FCC will further tighten the required location accuracy level in the near future [3]. This FCC mandate has motivated research efforts toward developing accurate wireless location algorithms and in fact has led to significant enhancements to the wireless location technology [e.g., 4–11].

2. *Location-Sensitive Billing*. Using accurate location information of wireless users, wireless service providers can offer variable-rate call plans that are based on the caller location. For example, the cell-phone call rate might vary according to whether the call was made at home, in the office, or on the road. This will enable wireless service providers to offer competitive rate packages to those of wire-line phone companies.

3. *Fraud Protection*. Cellular phone fraud has attained a notorious level, which serves to increase the usage and operation costs of cellular networks. This cost increase is directly passed to the consumer in the form of higher service rates. Furthermore, cellular fraud weakens the consumer confidence in wireless services. Wireless location technology can be effective in combating cellular fraud since it can enable pinpointing perpetrators.

4. *Person/Asset Tracking*. Wireless location technology can provide advanced public safety applications including locating and retrieving lost children, Alzheimer patients, or even pets. It could also be used to track valuable assets such as vehicles or laptops that might be lost or stolen. Furthermore, wireless location systems could be used to monitor and record the location of dangerous criminals.

5. *Fleet Management*. Many fleet operators, such as police force, emergency vehicles, and other services including shuttle and taxicab companies, can make use of the wireless location technology to track and operate their vehicles in an efficient way in order to minimize response times.

6. *Intelligent Transportation Systems*. A large number of drivers on road or highways carry cellular phones while driving. The wireless location technology can serve to track these phones, thus transforming them into sources of real-time traffic information that can be used to enhance transportation safety.

7. *Cellular System Design and Management*. Using information gathered from wireless location systems, cellular network planners could improve the cell planning of the wireless network based on call/location statistics. Improved channel allocation could be based on the location of active users [9,10].

8. *Mobile Yellow Pages*. According to the available location information, a mobile user could obtain road information of the nearest resource that the user might need such as a gas station or a hospital. Thus, a cellular phone will act as smart handy mobile yellow pages on demand. Cellular users could obtain real-time traffic information according to their locations.

¹The original FCC requirement was 125 m and was then tightened to 100 m.

3. WIRELESS LOCATION TECHNOLOGIES

Wireless location technologies fall into two main categories: mobile-based and network-based techniques. In mobile-based location systems, the mobile station determines its own location by measuring signal parameters of an external system, which can be the signals of cellular base stations or satellite signals of the Global Positioning System (GPS). On the other hand, network-based location systems determine the position of the mobile station by measuring its signal parameters when received at the network cellular base stations. Thus, in the later type of wireless location systems, the mobile station plays a minimal or no role in the location process.

3.1. Mobile-Based Wireless Location

3.1.1. GPS Mobile-Based Location Systems. In GPS-based location systems, the MS receives and measures the signal parameters of at least four different satellites of a currently existing network of 24 satellites that circle the globe at an altitude of 20,000 km and which constitute the Global Positioning System. Each GPS satellite transmits a binary code, which greatly resembles a code-division multiple-access (CDMA) code. This code is multiplied by a 50-Hz unknown binary signal to form the transmitted satellite signal. Each GPS satellite periodically transmits its location and the corresponding timestamp, which it obtains from a highly accurate clock that each satellite carries. The satellite signal parameter, which the MS measures for each satellite, is the time the satellite signal takes until it reaches the MS. Cellular handsets usually carry a less accurate clock than the satellite clock. To avoid any errors resulting from this clock inaccuracy, the MS timestamp is often added to the set of unknowns that need to be calculated, thus making the number of unknowns equal to four (three MS position coordinates plus timestamp). This is why four satellite signal parameters have to be measured by the MS. Further information on the GPS systems is available in the literature [12,13].

After measuring the satellite signal parameters, the MS can proceed in one of two manners. The first is to calculate its own position and then broadcast this position to the cellular network. Processing the measured signal parameter to obtain a position estimate is known as *data fusion*. In the other scenario, the MS broadcasts the unprocessed satellite signal parameters to another node (or server) in which the data fusion process is performed to obtain an estimate of the MS position. The later systems are known as *server-aided* GPS systems, while the first are known as “pure” GPS systems [14,15].

A general scheme for server-aided GPS systems is shown in Fig. 1. The server-aided GPS approach is successful in a microcellular environment, where the diameter of cellular cells is relatively small (a few hundred meters to a few kilometers). This environment is common in urban areas. On the other hand, in macrocell environments, which are common in suburban or rural areas, base stations, and thus servers, are widely spread out. This increases the average distance between the MS and the server leading to ineffective

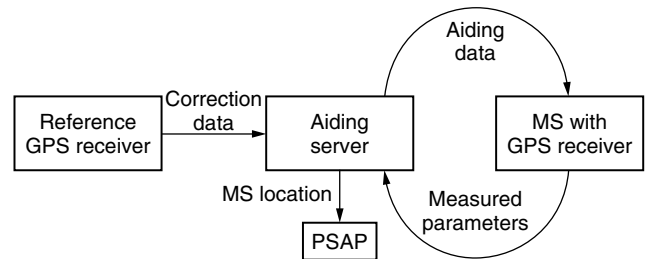

Figure 1. Server-aided GPS location.

correction information. This is why, in many mobile-based GPS location system designs, handsets have to support both server-aided GPS and pure GPS location modes of operation [e.g., 14].

GPS-based mobile location systems have the following advantages. GPS receivers usually have a relatively high degree of accuracy, which can reach less than 10 m with differential GPS server-aided systems [16]. Moreover, the GPS satellite signals are available all over the globe, thus providing global location information. Finally, GPS technology has been studied and enhanced for a relatively long time and for various applications, and is a rather mature technology. Despite these advantages, wireless service providers may be unwilling to embrace GPS fully as the principal location technology due to the following disadvantages of GPS-based location systems:

1. Embedding a GPS receiver in the mobile handset directly leads to increased cost, size, and battery consumption of the mobile handset.
2. The need to replace hundreds of millions of handsets that are already in the market with new GPS-aided handsets. This will directly impact the rates that the wireless carriers offer their users and can cause considerable inconvenience to both users and carriers during the replacement period.
3. The degraded accuracy of GPS measurements in urban environments, when one or more satellites are obscured by buildings, or when the mobile antenna is located inside a vehicle.
4. The need for handsets to support both server-aided and pure GPS modes of operation, which increases the average cost, complexity, and power consumption of the mobile handset. Furthermore, the power consumption of the handset can increase dramatically when used in the pure GPS mode. Moreover, the need to deploy GPS aiding servers in wireless base stations adds up to the total cost of GPS-aided location systems.
5. GPS-based location systems face a political issue raised by the fact that the GPS satellite network is controlled by the U.S. government, which reserves the right to shut GPS signals off to any given region worldwide. This might make some wireless service providers outside the United States unwilling to rely solely on this technology.

3.1.2. Cellular Mobile-Based Location Systems. Cellular mobile-based wireless location technology is similar to

GPS based location technology, in the sense that the MS uses external signals to determine its own location. However, in this type of location systems, the MS relies on wireless signals originating from cellular base stations. These signals could be actual traffic cellular signals or special-purpose probing signals, which are specifically broadcast for location purposes. Although this approach, which is also known as *forward-link wireless location*, avoids the need for GPS technology, it has the same disadvantages that GPS location systems have, which is the need to modify existing handsets, and may even have increased handset power consumption over that of the GPS solution. In addition, this solution leads to lower location accuracy than that of the GPS solution. This makes cellular mobile-based location systems less favorable to use by wireless service providers.

3.2. Network-Based Wireless Location

Network-based location technology depends on using the current cellular network to obtain wireless user location information. In these systems, the base stations (BSs) measure the signals transmitted from the MS and relay them to a central site for processing and calculating the MS location. The central processing site then relays the MS location information to the associated PSAP, as shown in Fig. 2. Such a technique is also known as *reverse-link wireless location*. Reverse-link wireless location has the main advantage of not requiring any modifications or specialized equipment in the MS handset, thus accommodating a large cluster of handsets already in use in existing cellular networks. The main disadvantage of network-based wireless location is its

relatively lower accuracy, when compared to GPS-based location methods [3].

Network-based wireless location techniques have the significant advantage that the MS is not involved in the location-finding process; thus these systems do not require any modifications to existing handsets. Moreover, they do not require the use of GPS components, thus avoiding any political issue that may arise from their use. However, unlike GPS location systems, many aspects of network-based location are not fully studied yet. This is due to the relatively recent introduction of this technology. In most of the rest of this article, we will focus on network-based wireless location. First, we will review the MS signal parameters that need to be estimated by the cellular base stations and how these signals are combined to obtain a MS location estimate, in data fusion, defined earlier. We will also discuss the sources of error that limit the accuracy of network-based location. Finally, we study different MS signal parameter estimation techniques along with some hardware implementation issues. Here, we may add that although many of the studied aspects apply to both GPS-based location and forward-link location, we will focus on reverse link network-based location. From this point on until the end of the article, we will refer to network-based wireless location simply as *wireless location*.

4. DATA FUSION METHODS

Data fusion for wireless location refers to combining signal parameter estimates obtained from different base stations to obtain an estimate of the MS location. We will study the conventional data fusion methods. The MS location coordinates in a Cartesian coordinate system are denoted by (x_0^o, y_0^o) , with the superscript 'o' used to denote quantities that are unknown and which we wish to estimate. These coordinates can be estimated from measured MS signal parameters, when measured at three or more base stations (BSs). The coordinates of the nearest three BSs to the MS, denoted by BS₁, BS₂, and BS₃, are (x_1, y_1) , (x_2, y_2) , and (x_3, y_3) , respectively. Without loss of generality, the origin of the Cartesian coordinate system is set to those of BS₁:

$$(x_1, y_1) = (0, 0)$$

We will denote the time instant at which the MS starts transmission as time instant t_0^o . This MS signal reaches the three BSs involved in the MS location process at instants t_1^o , t_2^o , and t_3^o , respectively. The amplitudes of arrival of the MS signal at the main and adjacent sectors of BS_{*i*} are respectively denoted by A_{i1}^o and A_{i2}^o , for $i = 1, 2, 3$.³ Data fusion methods obtain estimates for the MS coordinates, say, (x_0, y_0) , by combining the MS signals through

$$(x_0, y_0) = g(t_0, t_i, A_{i1}, A_{i2}) \quad (1)$$

³In cellular systems, a sectorized antenna structure is very common. Each BS usually contains three different antennas, with the main lobe of each antenna facing a different direction, and with an angle of 120° between each of the directions. The sector whose antenna faces a specific MS is termed the *main sector* serving this MS. The sector next to the main sector from the MS side is termed the *adjacent sector*.

Figure 2. Network-based wireless location.

where $\{t_0, t_i, A_{i1}, A_{i2}\}$ are estimates of $\{t_0^o, t_i^o, A_{i1}^o, A_{i2}^o\}$ and the function g depends on the data fusion method. The resulting location error from the data fusion operation is thus given by

$$e = \sqrt{(x_0 - x_0^o)^2 + (y_0 - y_0^o)^2} \quad (2)$$

One performance index, which is used to compare the accuracy of data fusion methods, is the location mean-square error (MSE), defined by

$$\text{MSE} = Ee^2 = E[(x_0 - x_0^o)^2 + (y_0 - y_0^o)^2] \quad (3)$$

Another performance index for data fusion methods is the value below which the error magnitude, $|e|$, lies for 67% of the time. In other words, it is the value of the error, $e_{67\%}$, at which the error cumulative density function (CDF) is equal to 0.67. The 67% error limit is the performance index that is used by the FCC to set the required location accuracy. Here we may add that for zero-mean Gaussian errors of variance σ_e^2 , we have

$$e_{67\%} = \sigma_e = \sqrt{\text{MSE}} \quad (4)$$

Several wireless location data fusion techniques have been introduced since the late 1990s, all of which are based on combining estimates of the time and/or amplitude of arrival of the MS signal when received at various BSs. These methods fall into the following categories:

- Time of arrival (ToA)
- Time difference of arrival (TDoA)
- Angle of arrival (AoA)
- Hybrid techniques

4.1. Time of Arrival (ToA)

The time of arrival (ToA) data fusion method is based on combining estimates of the time of arrival of the MS signal, when arriving at three different BSs. Since the wireless signal travels at the speed of light (C), thus the actual distance between the MS and BS_i , r_i , is given by

$$r_i^o = (t_i^o - t_0^o)C \quad (5)$$

where t_0^o is the actual time instant at which the MS starts transmission and t_i^o is the actual time of arrival of the MS signal at BS_i . Each ToA estimate, t_i , serves to form an estimate of the distance between the MS and the corresponding BS as

$$r_i = (t_i - t_0)C \quad (6)$$

These estimated distances between the MS and each of the three BSs are then used to obtain (x_0, y_0) by solving the following set of equations:

$$r_1^2 = x_0^2 + y_0^2 \quad (7)$$

$$r_2^2 = (x_2 - x_0)^2 + (y_2 - y_0)^2 \quad (8)$$

$$r_3^2 = (x_3 - x_0)^2 + (y_3 - y_0)^2 \quad (9)$$

Figure 3. Some wireless location techniques: (a) TOA and (b) AOA. The MS is positioned at the intersection of the loci.

Without loss of generality, it can be assumed that $r_1 < r_2 < r_3$.

Now, a conventional way of solving this overdetermined nonlinear system of equations is as follows. First, equations (7) and (8) are solved for the two unknowns (x_0, y_0) to yield two solutions. As shown in Fig. 3a, each equation defines a locus on which the MS must lie. Second, the distance between each of the two solutions and the circle, whose equation is given by (9) is calculated. Finally, the solution that results in the shortest distance from the circle (9) is chosen to be an estimate of the MS location coordinates [4].

Although this method will help resolve the ambiguity between the two solutions resulting from solving Eqs. (7) and (8), it does not combine the third measurement r_3 in an optimal way. Furthermore, it is not possible to combine more ToA measurements from BSs more than three.

This can be solved by combining all the available set of measurements using a least-squares approach into a more accurate estimate. This approach can be summarized as follows. Subtracting (7) from (8), we obtain

$$r_2^2 - r_1^2 = x_2^2 - 2x_2x_0 + y_2^2 - 2y_2y_0$$

Similarly, subtracting (7) from (9), we obtain

$$r_3^2 - r_1^2 = x_3^2 - 2x_3x_0 + y_3^2 - 2y_3y_0$$

Rearranging terms, the previous two equations can be written in matrix form as

$$\begin{bmatrix} x_2 & y_2 \\ x_3 & y_3 \end{bmatrix} \begin{bmatrix} x_0 \\ y_0 \end{bmatrix} = \frac{1}{2} \begin{bmatrix} K_2^2 - r_2^2 + r_1^2 \\ K_3^2 - r_3^2 + r_1^2 \end{bmatrix} \quad (10)$$

where

$$K_i^2 = x_i^2 + y_i^2 \quad (11)$$

Equation (10) can be rewritten as

$$\mathbf{H}\mathbf{x} = \mathbf{b} \quad (12)$$

where

$$\mathbf{H} = \begin{bmatrix} x_2 & y_2 \\ x_3 & y_3 \end{bmatrix}, \mathbf{x} = \begin{bmatrix} x_0 \\ y_0 \end{bmatrix}, \mathbf{b} = \frac{1}{2} \begin{bmatrix} K_2^2 - r_2^2 + r_1^2 \\ K_3^2 - r_3^2 + r_1^2 \end{bmatrix}$$

The solution of (12) is given by

$$\mathbf{x} = \mathbf{H}^{-1}\mathbf{b}$$

If more than three ToA measurements are available, it can be verified that (12) still holds, with

$$\mathbf{H} = \begin{bmatrix} x_2 & y_2 \\ x_3 & y_3 \\ x_4 & y_4 \\ \vdots & \vdots \end{bmatrix}, \mathbf{b} = \frac{1}{2} \begin{bmatrix} K_2^2 - r_2^2 + r_1^2 \\ K_3^2 - r_3^2 + r_1^2 \\ K_4^2 - r_4^2 + r_1^2 \\ \vdots \end{bmatrix}$$

In this case, the least-squares solution of (12) is given by

$$\mathbf{x} = (\mathbf{H}^T \mathbf{H})^{-1} \mathbf{H}^T \mathbf{b} \quad (13)$$

The ToA method requires accurate synchronization between the BSs and MS clocks. Many of the current wireless system standards only mandate tight timing synchronization among BSs [e.g., 17]. However, the MS clock might have a drift that can reach a few microseconds. This drift directly reflects into an error in the location estimate of the ToA method.

4.2. Time Difference of Arrival (TDoA)

Another widely used technique that avoids the need for MS clock synchronization is based on time difference of arrival (TDoA) of the MS signal at two BSs. Each TDoA measurement forms a hyperbolic locus for the MS. Combining two or more TDoA measurements results in a MS location estimate that avoids MS clock synchronization errors [e.g., 18–21].

We now illustrate how a closed-form location solution can be obtained from TDoA measurements in the case of three BSs involved in the MS location. The TDoA measurement between BS_i and BS₁ is defined by

$$r_{i,1} \triangleq r_i - r_1 \\ = (t_i - t_0)C - (t_1 - t_0)C = (t_i - t_1)C \quad (14)$$

Note that TDoA measurements are not affected by errors in the MS clock time (t_0) as it cancels out when subtracting two ToA measurements. Equation (8) can be rewritten, in terms of the TDoA measurement $r_{2,1}$, as

$$(r_{2,1} + r_1)^2 = K_2^2 - 2x_2x_0 - 2y_2y_0 + r_1^2$$

Expanding and rearranging terms, we get

$$-x_2x_0 - y_2y_0 = r_{2,1}r_1 + \frac{1}{2}(r_{2,1}^2 - K_2^2)$$

Similarly, we can write

$$-x_3x_0 - y_3y_0 = r_{3,1}r_1 + \frac{1}{2}(r_{3,1}^2 - K_3^2)$$

Rewriting these equations in matrix form we get

$$\mathbf{H}\mathbf{x} = \mathbf{c}r_1 + \mathbf{d} \quad (15)$$

where

$$\mathbf{c} = \begin{bmatrix} -r_{2,1} \\ -r_{3,1} \end{bmatrix}, \mathbf{d} = \frac{1}{2} \begin{bmatrix} K_2^2 - r_{2,1}^2 \\ K_3^2 - r_{3,1}^2 \end{bmatrix}$$

This equations can be used to solve for \mathbf{x} , in terms of the unknown r_1 , to get

$$\mathbf{x} = \mathbf{H}^{-1}\mathbf{c}r_1 + \mathbf{H}^{-1}\mathbf{d}$$

Substituting this intermediate result into (7), we obtain a quadratic equation in r_1 . Substituting the positive root back into the above equation yields the final solution for \mathbf{x} .

If more than three BSs are involved in the MS location, Eq. (15) still holds with

$$\mathbf{H} = \begin{bmatrix} x_2 & y_2 \\ x_3 & y_3 \\ x_4 & y_4 \\ \vdots & \vdots \end{bmatrix}, \mathbf{c} = \begin{bmatrix} -r_{2,1} \\ -r_{3,1} \\ -r_{4,1} \\ \vdots \end{bmatrix}, \mathbf{d} = \frac{1}{2} \begin{bmatrix} K_2^2 - r_{2,1}^2 \\ K_3^2 - r_{3,1}^2 \\ K_4^2 - r_{4,1}^2 \\ \vdots \end{bmatrix}$$

which yields the following least-squares intermediate solution

$$\mathbf{x} = (\mathbf{H}^T \mathbf{H})^{-1} \mathbf{H}^T (\mathbf{c}r_1 + \mathbf{d}) \quad (16)$$

Combining this intermediate result with (7), the final estimate for \mathbf{x} is obtained. A more accurate solution can be obtained as in Ref. 19 if the second-order statistics of the TDoA measurement errors are known.

4.3. Angle of Arrival (AoA)

In cellular systems, AoA estimates can be obtained by using antenna arrays. The direction of arrival of the MS signal can be calculated by measuring the phase difference between the antenna array elements or by measuring the power spectral density across the antenna array in what is known as *beamforming* (see, e.g., reference [22] and the works cited therein). Combining the AoA estimates of two BSs, an estimate of the MS position can be obtained (see Fig. 3b). Thus the number of BSs needed for the location process is less than that of ToA and TDoA methods by one. Another advantage of AoA location methods is that they do not need any BS clock synchronization. However, one disadvantage of using antenna-array-based location methods is that antenna array structures do not currently exist in second-generation (2G) cellular systems. Deploying antenna arrays in all existing BSs may lead to high cost burdens on wireless service providers. The use of antenna arrays is planned in some third-generation (3G) cellular systems, such as Universal Mobile Telecommunications System (UMTS) networks [e.g., 23,24], which will use antenna arrays to provide directional transmission in order to improve the network capacity.

AoA estimates can also be obtained using sectorized multibeam antennas, which already exist in current cellular systems, using the technique described in reference [25]. In this technique, an estimate of the AoA ($\hat{\theta}$ — see Fig. 4) is obtained based on the difference between the measured signal amplitude of arrival (AmpoA) at the main beam (beam 1) and the corresponding AmpoA

measured at the adjacent beam (beam 2).⁴ This difference is denoted by $A_1 - A_2$ in Fig. 5, where A_1 and A_2 are the measured amplitude levels in decibels. The measured AmpoA at the third beam may be used to resolve any ambiguity that might result from antenna sidelobes. One main challenge facing this technique is the relatively low signal-to-noise ratio (SNR) of the received MS signal at the adjacent beam, especially in cases where the AoA is close to a null in the adjacent beam field pattern (e.g., θ close to 0 degrees in Figs. 4 and 5). This significantly limits the AmpoA estimation accuracy at the adjacent beam.

4.4. Hybrid Techniques

In ToA, TDoA, and AoA methods, two or more BSs are involved in the MS location process. In situations where

Figure 4. Sected-antenna field pattern.

Figure 5. Measured AmpOA level patterns (in dB) for a three-beam antenna versus the AOA (θ).

⁴ Here, *main beam* denotes the beam with the highest received signal level and *adjacent beam* refers to the beam that receives the second highest signal level.

the MS is much closer to one BS (serving site) than the other BSs, the accuracy of these methods is significantly degraded because of the relatively low SNR of the received MS signal at one or more BSs. Such accuracy is further reduced due to the use of power control, which requires the MS to reduce its transmitted power when it approaches a BS, causing what is known as the *hearability* problem [26]. Such problems will be discussed in the next section. In these cases, an alternate location procedure is to obtain an angle of arrival estimate (AoA) from the serving site and combine it with a ToA estimate of the serving site [27]. Combining ToA and AoA estimates from one BS leads to one well-defined MS position estimate, which corresponds to the intersection of a circle and a straight line that starts at the center of the circle. The precision of this hybrid technique is limited by the accuracy of the ToA measurement, which is dictated by the accuracy of the MS clock. Many other hybrid location data fusion techniques can be used, such as combining TDoA and AoA measurements [28].

5. SIGNAL PARAMETER ESTIMATION

From the previous discussion, we can see that the wireless location methods depend on combining estimates of the ToA and/or AoA of the received signal at/from different BSs. Although estimating the time and amplitude of arrival of wireless signals has been studied in many works since 1990 as it is needed in many cellular systems for online signal decoding purposes [29], parameter estimation for wireless location is actually a different estimation problem in many respects. This makes the success of using conventional estimation algorithms very limited in wireless location problems. In this section, we will illustrate the differences between signal parameter estimation for conventional signal decoding and wireless location. We will then discuss some particular system issues that makes signal estimation for wireless location different from one cellular system to the other (e.g., GSM, 2G and 3G CDMA systems).

Signal parameter estimation for wireless location purposes is different than that for online signal decoding in the following aspects:

1. *Lower SNRs.* Cellular systems usually suffer from high multiple-access interference levels that degrade the SNR of the received signal, thus degrading the signal parameter estimation accuracy in general. Moreover, for network-based wireless locations, the ability to detect the MS signal at multiple base stations is limited by the use of power control algorithms, which require the MS to decrease its transmitted power when it approaches the serving BS. This significantly decreases the received MS signal power level, when received at other BSs involved in the location process. This scenario is shown in Fig. 6, where the received SNRs at BS₁ and BS₂ are significantly reduced as the target MS approaches BS₃. In a typical CDMA IS95 cellular environment, the received SNR of the serving BS is in the order of -15 dB. Conventional signal estimation algorithms are usually designed to work at this SNR level. However, the received SNR at BSs other than

Figure 6. Multiple-access interference among adjacent cells in cellular systems. The letters BS indicate the base stations and the letters MS denote the target mobile station.

the main serving BS can be as low as -40 dB, which poses a challenge for wireless location in such environments.

2. Almost Perfect Knowledge of Transmitted Signals. In conventional signal parameter estimation for online signal decoding, the transmitted MS bits are unknown. This forces signal estimation algorithms to perform a squaring operation to remove any bit ambiguity. The squaring operation limits the period over which coherent signal integration (averaging) is possible to the bit period. Further signal integration is only possible in a noncoherent manner, that is averaging after squaring. In wireless location applications, signal estimation algorithms can have almost perfect knowledge of the MS signal in many cases. For example, at the serving site, the MS signal is decoded with reasonably high accuracy (within a 1% frame error rate). The decoded bits become ready for use after a delay that is equal to the decoded frame period used in the cellular system (20 ms for IS95 systems). Because of the nature of wireless location applications, such a delay is not critical. Thus, the received MS signal can be *buffered* or delayed until the decoded bits become available through the conventional decoding process. Moreover, in many cellular systems, a cyclic redundancy check (CRC) feature is used. This enables the decoder to point out the erroneous frames after the decoding process. These erroneous frames can be ignored in the signal estimation process. The decoded bit information, obtained from the main sector of the serving site, can also be used by other adjacent sectors of the same site. Furthermore, this bit information can be transmitted through the network infrastructure to other BSs involved in locating the MS. This is known as *tape recording* of the MS signal. Another technique that avoids the tape recording process is known as the *powerup function* (PuF), which requires the MS in emergency situations to override the power control commands and raise its transmitted power level above the conventional level. Moreover, the MS transmits *known* probing bit sequences instead of its regular unknown bit sequence for a part or all of the transmission period. Although this solution overcomes many of the difficulties

encountered at far BSs, it requires modifying the existing handsets or at least the used power control algorithms. Furthermore, it can cause a decrease in the overall network capacity [26].

3. Channel Fading. Channel fading is considered constant during the relatively short estimation period of conventional signal parameter algorithms for online signal decoding, and is thus ignored in the design of such algorithms. This assumption cannot be made for wireless location applications where the estimation period could be *considerably longer* (might reach a few seconds). Furthermore, coherent integration periods are no longer limited by the bit duration, much longer coherent averaging periods could be achieved in wireless location applications [30,31]. In this case, the coherent integration period is limited by the received signal phase rotation. Thus, unlike the case of online channel estimators, channel fading plays an important role in any successful design of signal parameter estimators for wireless location. In many cases, the system parameters have to be adapted to the available knowledge of the channel fading characteristics.

4. Need to Resolve Overlapping Multipath. Multipath propagation is often encountered in wireless channels (see, e.g., the paper [32] and the references cited therein). In wireless location systems, the accurate estimation of the time and amplitude of arrival of the *first arriving ray* of the multipath channel is vital. In general, the first arriving (prompt) ray is assumed to correspond to the most direct path between the MS and the BS. However, in many wireless propagation scenarios, the prompt ray is succeeded by a multipath component that arrives at the receiver within a short delay from the prompt ray. If this delay is smaller than the duration of the pulse-shape used in the wireless system, these two rays overlap causing significant errors in the prompt ray time and amplitude of arrival estimation. Resolving these overlapping multipath components becomes rather difficult in low SNR and rapid channel fading situations. On the other hand, resolving these overlapping components is not vital for signal decoding applications as it does not significantly affect the performance of the signal decoding operation, for which *coarse* estimates for the channel time delays and amplitudes are sufficient.

Figure 7 shows an example for the combined impulse response of a two-ray channel and a conventional pulseshape for a conventional CDMA IS95 system in two cases (a,b). In case (a), the delay between the two channel rays is equal to twice the chip duration ($2T_c$). It is clear that the peaks of both rays are resolvable, by a simple peak picking procedure, thus allowing for relatively accurate estimation of the prompt ray time and the amplitude of arrival. However, in case (b), both multipath components overlap and are *nonresolvable* via peak picking. This can lead to significant errors in the prompt ray time and amplitude of arrival estimation. These errors cannot be tolerated for wireless location applications, especially in the case of a relatively wide pulseshaping waveform.

5.1. Parameter Estimation Schemes

We now elaborate on some schemes that are used to estimate the wireless signal time and amplitude of arrival.

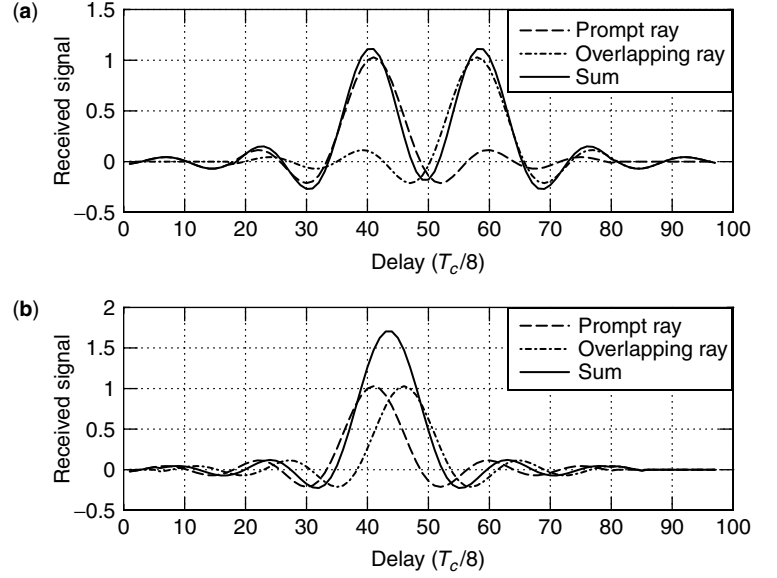

Figure 7. Overlapping rays: (a) delay = $2T_c$; (b) delay = $T_c/2$.

The aim of such schemes is to estimate an unknown constant discrete-time delay, τ^o , of a known real-valued sequence $\{s(n)\}$. The signal is transmitted over a single-path time-varying channel, and the designer has access to a measured sequence $\{r(n)\}_{n=1}^K$ that relates to $\{s(n)\}$ via

$$r(n) = Ax^o(n)s(n - \tau^o) + v(n) \quad (17)$$

where $v(n)$ is additive white Gaussian noise, and $\{x^o(n)\}$ accounts for the time-varying nature of the *fading* channel gain over which the sequence $\{s(n)\}$ is transmitted, while A is a constant *unknown* received signal amplitude that accounts for both the gain of the *static* channel if fading were not present and the antenna beam gain. Multipath issues are considered later in this section.

A conventional estimation scheme for τ^o for online bit decoding purposes is shown in Fig. 8. In this scheme, the received sequence, $r(n)$, is correlated with replicas of $\{s(n - \tau_i)\}$ over a grid of τ values, say, $\{\tau_1, \tau_2, \dots, \tau_F\}$. The coherent averaging period, N , is set to the bit interval. The outputs of the correlation process are squared to remove any bit ambiguity and then noncoherently averaged over the rest of the available estimation period.

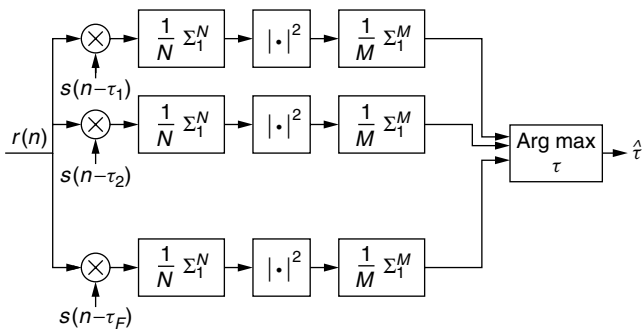

Figure 8. Conventional time-delay estimation for single-path channels.

Figure 9 shows a block diagram of a wireless location ToA/AoA estimation scheme [30]. In this scheme, the received sequence $\{r(n)\}$ is also multiplied by a replica of the transmitted sequence $\{s(n - \tau)\}$ for different values of τ . The resulting sequence is then averaged coherently over an interval of N samples, and further averaged noncoherently for M samples to build a power delay profile, $J(\tau)$. The averaging intervals N and M are positive integers that satisfy $K = NM$, and the value of N is picked adaptively in an optimal manner by using an estimate of the maximum Doppler frequency of the fading channel (\hat{f}_D), which can be estimated using some suggested techniques [e.g., 33].

The searcher picks the maximum of $J(\tau)$, which is given by

$$J(\tau) = \frac{1}{M} \sum_{m=1}^M \left| \frac{1}{N} \sum_{n=(m-1)N+1}^{mN} r(n)s(n - \tau) \right|^2 \quad (18)$$

and assigns its index to the ToA estimate, according to

$$\hat{\tau}^o = \arg \max_{\tau} J(\tau) \quad (19)$$

The optimal value of the coherent averaging period (N_{opt}) is obtained by maximizing the SNR gain at the output of the estimation scheme with respect to N which leads to [30]

$$\sum_{i=1}^{N_{\text{opt}}-1} i R_x(i) = 0 \quad (20)$$

where $R_x(i)$ is the autocorrelation function of the sequence $\{x(n)\}$. For a Rayleigh fading channel, $R_x(i)$ is given by

$$R_x(|i|) = J_0(2\pi f_D T_s i)$$

where $J_0(\cdot)$ is the first-order Bessel function, T_s is the sampling period of the received sequence $\{r(n)\}$, and f_D is

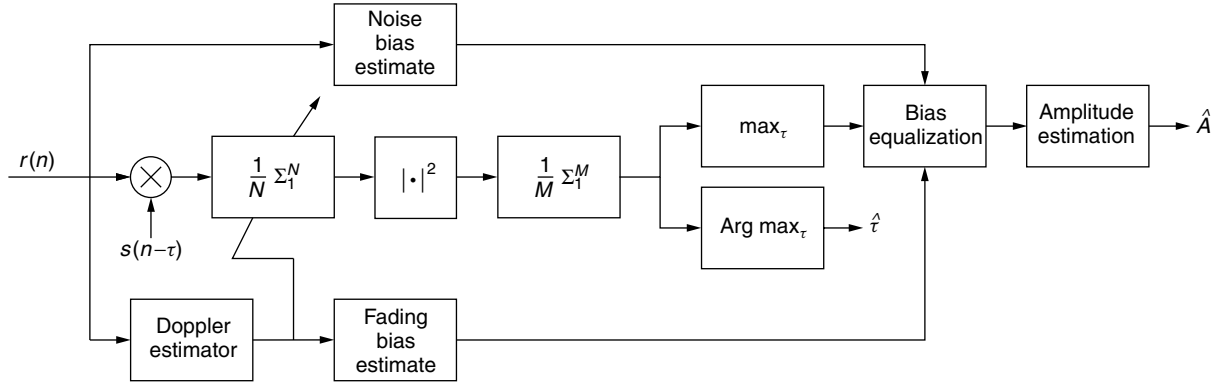

Figure 9. A time-delay estimation scheme for single-path fading channels.

the maximum Doppler frequency of the Rayleigh fading channel. Equation (20) shows that the coherent averaging interval N should be adapted according to the channel autocorrelation function.

It has been shown [30,31] that when coherent/non-coherent averaging estimation schemes are used for wireless location applications, where an extended coherent averaging interval is used, two biases arise at the output of the estimation scheme. Both biases affect the accuracy of the amplitude estimate significantly. The first bias is an additive noise bias that increases with the noise variance and is given by

$$B_n = \frac{\sigma_v^2}{N} \quad (21)$$

The second bias is a multiplicative fading bias that depends on the autocorrelation function and is given by

$$B_f = \frac{R_x(0)}{N} + \sum_{i=1}^{N-1} \frac{2(N-i)R_x(i)}{N^2} \quad (22)$$

It is clear that B_f is less than or equal to unity (it is unity for static channels, which explains why previous conventional designs ignored this bias as fading was not considered in these designs [29]; the value of B_f is also unity for $N = 1$).

To correct for these biases, the searcher equalizes the peak value of $J(\tau)$ by subtracting two fading and noise biases, which are estimated by means of the upper and lower branches of the scheme of Fig. 9. The output of this correction procedure is taken as an estimate for the amplitude of arrival, which is given by

$$A = \sqrt{C_f[J(\tau^o) - B_n]}$$

The value of C_f (the fading correction factor) is $C_f = 1/B_f$:

$$C_f = \left[\frac{R_x(0)}{N} + \sum_{i=1}^{N-1} \frac{2(N-i)R_x(i)}{N^2} \right]^{-1} \quad (23)$$

For a Rayleigh fading channel, this correction factor increases with the maximum Doppler frequency of the fading channel. When f_D is estimated, we actually end up

with an estimate for C_f . For the case of CDMA systems, the quantity B_n can be estimated as follows. Note first that the noise variance σ_v^2 can be estimated *directly* from the received sequence $\{r(n)\}$ since, for CDMA signals, the SNR is typically very low. In other words, we can get an estimate for σ_v^2 as follows:

$$\hat{\sigma}_v^2 = \frac{1}{K} \sum_{i=1}^K |r(i)|^2$$

Then, an estimate for B_n is given, from (21), by

$$\hat{B}_n = \frac{\hat{\sigma}_v^2}{N} = \frac{1}{NK} \sum_{i=1}^K |r(i)|^2 \quad (24)$$

With $\{\hat{B}_n, C_f\}$ so computed, we obtain an estimate for A via the expression

$$\hat{A} = \sqrt{C_f[J(\tau^o) - \hat{B}_n]} \quad (25)$$

More details on this scheme and simulation results can be found in the literature [30,31,34].

5.2. Overlapping Multipath Resolving

As mentioned before, wireless propagation usually suffers from severe multipath conditions. In situations where the prompt ray overlaps with a successive ray, a significant error in both the time and amplitude of arrival estimation is encountered.

Overlapping multipath components can be modeled by considering the relation

$$r(n) = c(n) * p(n) * h(n) + v(n) \quad (26)$$

where $\{r(n)\}$ continues to denote the received sequence, $\{c(n)\}$ is a known binary sequence, $\{p(n)\}$ is a known pulse-shape impulse response sequence, $v(n)$ is additive white Gaussian noise of variance σ_v^2 , and $h(n)$ now refers to a multipath channel that is described by

$$h(n) = \sum_{l=1}^L \alpha_l x_l(n) \delta(n - \tau_l^o) \quad (27)$$

Here α_l , $\{x_l(n)\}$, and τ_l^o are respectively the unknown gain, the normalized amplitude sequence, and the time of arrival of the l th multipath component (ray). The above model assumes that there is a multipath component at each delay with corresponding amplitude α_l . In practice, most of these amplitudes will be zero or insignificant. For this reason, a common procedure is to estimate the amplitudes at all delays and to compare them to a threshold value that is proportional to the noise variance. If the amplitude α_l , at a specific delay τ_l^o , is larger than the threshold, then it is declared to correspond to a multipath component. The time and amplitude of arrival are then taken as the time and amplitude of the earliest ray higher than this threshold.

In this regard, the required estimation problem is one of estimating the vector of amplitudes at all possible delays, which is given by

$$\mathbf{h} \triangleq \text{col}[\alpha_1, \alpha_2, \dots, \alpha_L]$$

Several least-squares-type methods have been suggested for this purpose [35–37]. These methods exploit the known transmitted pulse-shape to resolve overlapping rays. For example, it has been shown [37] that, under some reasonable assumptions, the vector \mathbf{h} can be estimated by means of the following procedure. The received sequence is multiplied by delayed replica of the known transmitted sequence, $\{s(n - \tau)\}$. Each N sample of the resulting sequence is coherently averaged and the resulting averages at all delays are collected into a vector, say, \mathbf{r} . An estimate of \mathbf{h} is then obtained from \mathbf{r} by solving a least-squares problem, which leads to

$$\hat{\mathbf{h}} = (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T \mathbf{r} \quad (28)$$

where \mathbf{A} denotes a convolution matrix that is constructed from the pulse-shaping waveform. A general block diagram for such least-squares based techniques is shown in Fig. 10. Alternative so-called *superresolution* techniques are also available that are based on methods known as ESPRIT and MUSIC (see the paper [22] and references cited therein).

Least-squares multipath resolving techniques, however, suffer from noise boosting, which is usually caused by the ill conditioning of the matrices involved in the LS operation. This ill-conditioning magnifies the noise at the output of the LS stage. For wireless location finding applications, where the received signal-to-noise ratio (SNR) is relatively low, noise magnification leads to significant errors in the time and amplitude of arrival estimates, which in turn result in low location precision. Other modified LS techniques that attempt to avoid matrix ill conditioning—such as regularized least-squares, total

least-squares, and singular value decomposition methods—lack the required fidelity to resolve overlapping multipath components. Furthermore, applying least-squares methods may produce unnecessary errors in the case of single-path propagation.

An adaptive filtering technique for multipath resolving that avoids the aforementioned difficulties has been discussed [38]. Although adaptive filters do not suffer from noise amplification, they can still suffer from slow convergence and also divergence in some cases. These problems can be addressed by using knowledge about the channel autocorrelation and the fact that each channel ray fades at a different Doppler frequency.

6. HARDWARE IMPLEMENTATION ISSUES

It is clear from the previous considerations that signal parameter estimation for wireless location purposes often requires performing an extensive search over a dense grid of the estimated parameter (e.g., ToA estimation). The hardware implementation of these search schemes requires special attention as they might introduce a dramatic increase in the overall system hardware complexity and power consumption. In this section we review two hardware architectures for implementing ToA estimation schemes. The first scheme depends on combining the hardware of both channel and location searchers, while the second involves a Fast Fourier Transform (FFT)-based estimation scheme. Both architectures aim at reducing the overall hardware complexity.

6.1. Combined Channel/Location Searchers

A main hardware block in CDMA receivers is the conventional RAKE receiver, which consists of a dedicated channel searcher and a minimum of three RAKE fingers. Channel searchers obtain coarse estimates of the time and amplitude of arrival of the strongest multipath components of the MS signal. This information is then used by the receiver RAKE fingers and delay-locked loops (DLLs) to lock onto the strongest channel multipath components, which are combined and used in bit decoding. Estimates of the time and amplitude of arrival of the strongest rays are continuously fed from the channel searcher to the RAKE fingers.

Although the location searcher and RAKE receiver differ in purpose, structure, and estimation period, several basic building hardware blocks used in each of them are common. This fact can be exploited to combine both searchers into a single architecture that serves to save hardware blocks with added design flexibility.

Figure 11 shows the scheme, proposed in another paper [39], for the combined searcher architecture. The

Figure 10. Multipath least-squares searcher.

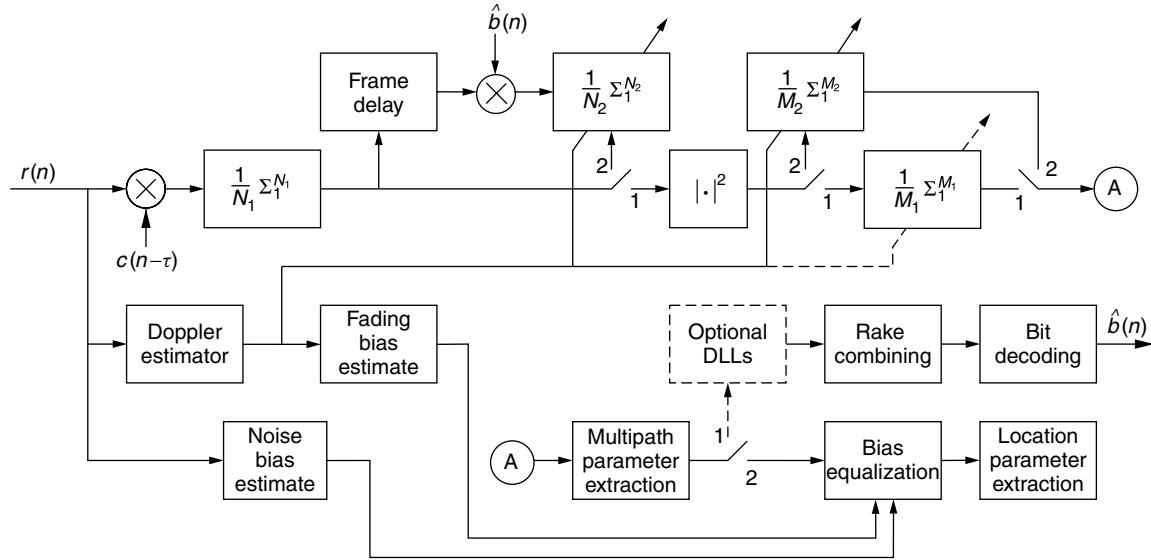

Figure 11. Combined architecture for location searcher and RAKE receiver.

scheme is formed from L_f data branches. Each data branch starts with a correlator over N_1 samples (despreader), where N_1 is the number of chips per symbol multiplied by the number of data samples per chip (4, 8, or 16). The output of the correlator is then multiplexed between two paths, marked “1” and “2” in Fig. 11. In path 1, which corresponds to data path of the channel searcher or RAKE finger branches, the despread signal is squared and noncoherently averaged over M_1 samples, where M_1 is *optionally* adapted to an estimate of the maximum Doppler frequency of the fading channel. For path 2, which is needed for the location parameter estimation, the despread sequence is delayed for a frame period, multiplied by an estimate of the transmitted bit sequence, coherently averaged over N_2 samples, squared, and noncoherently averaged over M_2 samples. Both N_2 and M_2 are adapted according to an estimate of the maximum Doppler frequency. The output of either paths is used to extract the channel multipath parameters.

The dynamic operation of the scheme is as follows. The received sequence is despread by multiplying by delayed code replica $c(n - \tau)$ and averaged over N_1 samples after which the N_1 register is reset. For online bit decoding, samples of the despread sequence are squared and noncoherently averaged. The average of every M_1 samples is passed to the multipath parameter extraction block and the M_1 register is then reset. Coarse multipath rays information are continuously fed to the L_f RAKE fingers, which use $3L_f$ branches of the scheme to obtain *early, on-time, and late* correlations over M_1 symbols. Such correlations are needed to advance or delay the sampling timing to lock onto the correct sampling point. This is done according to the difference between the early and late correlations [40]. The outputs of these fingers are combined, and used in bit decoding. Optional DLLs can be used to further enhance the tracking performance of the RAKE fingers. For location parameter estimation, the despread sequence is delayed, multiplied by an estimate

of the transmitted bit sequence $\hat{b}(n)$, and continuously averaged over N_2 symbols. Every N_2 symbols, the N_2 register is reset and its output is squared using the shared squaring circuits and averaged over M_2 samples. After the total location estimation period ($N_2 \times M_2$ symbols), the time and amplitude of arrival of the prompt ray are equalized for fading and noise biases and used to extract needed location parameters.

This architecture has the following advantages:

1. Saving a large number of hardware building blocks via multiplexing basic hardware blocks between $3L_f + L_c$ location searcher and RAKE receiver branches.
2. Improving the performance of the RAKE receiver by continuously adapting the estimation period M_1 to an estimate of the maximum Doppler frequency. This period is conventionally adjusted to track a fading channel in the worst (fastest) case, which restricts this period to a small value (around 6 symbols for IS95 systems). Adapting the estimation period of the channel searcher has two advantages: (a) it will increase the accuracy of the delay and amplitude estimates, and (b) it will help save power as it will reduce the number of times the RAKE fingers need to change their lock point, especially for low maximum Doppler frequency cases.
3. Reducing the hardware complexity significantly by eliminating the need to use DLLs for fine tracking in the cases where the accuracy of the used combined architecture is $T_c/8$ or higher (which is typical for location applications). In such cases the accuracy of the RAKE receiver will be adequate for online bit decoding without the use of DLLs. Hardware implementation of DLLs is extremely complex, especially with regard to the analog front end [40].

Further details of the operation of this architecture is given in [39], along with performance simulation results.

6.2. FFT-Based Searchers

In mobile-based wireless location systems, a maximum-likelihood searcher is embedded in the MS handset. It is very common for such searchers to involve multiple *correlation* operations of the received signals, from cellular BSs or GPS satellites, with local delayed replica of the transmitted signals. Performing these extensive correlations in the time domain may be a burden for the MS hardware. Often these correlations are performed using a general-purpose DSP processor, which is embedded in the MS to perform many other tasks, including the correlation process. DSP processors have many advantages, such as low cost, versatility, and design flexibility. An efficient way of implementing correlation operations in this case is through the use of fast Fourier transform (FFT). FFT-based location searchers have shown significant efficiency when implemented on DSP processors [e.g., 15,41].

We now review the basic principles of operation of FFT-based location searchers. The output of the correlation operation, say, $y(\tau)$, between two sequences, $\{r(n)\}$ and $\{s(n)\}$, can be viewed as a sum of the form

$$y(\tau) = \sum_{n=1}^N r(n)s(n - \tau)$$

Evaluating this sum requires N multiplication operations for every value of the delay τ . Thus, computing $y(\tau)$ in the time domain needs N^2 multiplications. On the other hand, the correlation operation can be viewed as a multiplication of two sequences in the frequency domain, which has the form

$$Y(\omega) = R(\omega) \cdot S(\omega)$$

where $Y(\omega)$, $R(\omega)$, and $S(\omega)$ are the Fourier transforms of $y(\tau)$, $r(n)$, and $s(n)$, respectively. Thus, an alternate way of computing $y(\tau)$, is via

$$y(\tau) = \mathcal{F}^{-1}[R(\omega) \cdot S(\omega)].$$

Thus, the total number of multiplications needed to perform this operation is the number of multiplications needed to obtain the FFT of the sequences $r(n)$ and $s(n)$, the product of $R(\omega)$ and $S(\omega)$, and finally the inverse FFT of this product. Notice that if the sequence $s(n)$ is perfectly known, its FFT can also be known and stored instead of storing the signal $s(n)$ itself. Thus the total number of multiplications needed is given by $(N + N \log_2 N)$. When N is relatively large, this number of multiplications can be significantly less than N^2 . For example, correlating GPS signals of length 1024 using the FFT approach is faster than performing the correlation in the time domain by a factor of 64 [15,41]. This directly reflects to a huge saving in the complexity and power consumption of the MS handset. We may also note that this procedure works only for sequences whose length is a power of 2. The general case can still be efficiently treated using the chirp-z transform (CZT), which can handle sequences whose length is not a power of two (See Refs. 15 and 41 for more details).

7. CONCLUDING REMARKS

As can be inferred from the discussions in the body of the article, and from the extended list of references below, wireless location is an active field of investigation with many open issues and with a variety of possible approaches and techniques. The final word is yet to come, which opens the road to much further work and, ultimately, to tremendous benefits.

Acknowledgments

This work was partially supported by the National Science Foundation under Award numbers CCR-9732376 and ECS-9820765. The authors would also like to thank Dr. L. M. A. Jalloul for his input, insights and collaboration in this area of research.

BIOGRAPHIES

Ali H. Sayed received his B.S. and M.S. degrees in electrical engineering from the University of Sao Paulo, Brazil, and his Ph.D. degree in electrical engineering in 1992 from Stanford University. He is professor of electrical engineering at the University of California, Los Angeles. He has over 170 publications, is the coauthor of two published books and the coeditor of a third book. He sits on the editorial boards of several journals including the *IEEE Transactions on Signal Processing*, the *SIAM Journal on Matrix Analysis and Its Applications*, and the *International Journal of Adaptive Control and Signal Processing*. He is also a member of the technical committees on signal processing theory and methods (SPTM) and on signal processing for communications (SPCOM), both of the IEEE Signal Processing Society. He has contributed several articles to engineering and mathematical encyclopedias and handbooks, and has served on the program committees of several international meetings. He has also consulted with industry in the areas of adaptive filtering, adaptive equalization, and echo cancellation. His research interests span several areas including adaptive and statistical signal processing, filtering and estimation theories, equalization techniques for communications, interplays between signal processing and control methodologies, and fast algorithms for large-scale problems. Dr. Sayed is a recipient of the 1996 IEEE Donald G. Fink Award and is a fellow of IEEE.

Nabil R. Yousef received his B.S. and M.S. degrees in electrical engineering from Ain Shams University, Cairo, Egypt, in 1994 and 1997, respectively, and his Ph.D. in electrical engineering from the University of California, Los Angeles, in 2001. He is currently a senior research staff member at Broadcom Corp., Irvine, California. His research interests include adaptive filtering, equalization, CDMA systems, and wireless location. He is a recipient of a 1999 Best Student Paper Award at an international meeting for work on adaptive filtering, and of a 1999 NOKIA Fellowship Award.

WIRELESS MPEG-4 VIDEOCOMMUNICATIONS*

MADHUKAR BUDAGAVI
Texas Instruments, Incorporated
Dallas, Texas

1. INTRODUCTION

With the success of personal mobile wireless phones for voice communications, there is now wide commercial interest and activity in extending the capabilities of the mobile phone to support videocommunications. Addition of video functionality to mobile phones leads to several new applications of the mobile phone—these include videotelephony, streaming video, video e-postcards and messaging, surveillance, and distance learning and collaboration. Mobile videotelephony enables users to not only talk to each other anywhere and at any time they want to, but it also allows them to see each other at the same time. Streaming video turns the mobile phone into a mobile entertainment device—it enables users to watch news and sports clips, music videos, and movie clips at any place and at any time they want to. It also allows mobile phone users to watch the video streaming from their home camera for surveillance purposes. Support for sending video e-postcards and messages in mobile phones enables users, for example, to send their vacation videos and photos directly from their vacation spots itself. Support for receiving instant video messages enables users to be immediately notified of any security event detected on their home surveillance camera. Users can take a look at the video of the security event enclosed with the instant video message and decide what action to take. Users can also use their video-enabled mobile phones to look at real-time educational lectures and videos and get trained on their long commute to work on trains. They can also use the video-enabled mobile phone to remotely collaborate from a worksite; for instance, they can use their mobile videophone to send real-time images of ongoing construction to their colleagues in their office and collaborate. One can similarly think of many other applications of a video-enabled mobile phone or device.

Wireless videocommunications is a multifaceted problem covering the fields of signal processing, wireless communications, data compression, transport protocols, and microelectronics. Supporting video transmission on wireless channels involves many technical challenges. Raw digital video data require a large amount of bandwidth; for instance, even a low-resolution (176×144 -pixel) color video sequence at 15 frames per second (fps) requires 4.5 megabits per second (Mbps). The bandwidth available on current wireless channels is limited and also expensive. Hence it becomes important that the video data be compressed prior to transmission over wireless channels. Video sequences have redundancies in both the temporal (i.e., between adjacent video frames) and the spatial (i.e., within a video frame) domains. Video compression is achieved by removing these redundancies. Standard video compression algorithms usually make use of the following three steps to achieve efficient compression:

1. Predict the current video frame from the previous video frame (by using motion vectors) to remove temporal redundancy.
2. Then use the energy-compacting discrete-cosine transform (DCT) to encode spatial redundancy.
3. Finally, use entropy coding (variable-length coding) to encode the various parameters resulting from steps 1 and 2.

Advances in low-bit-rate video coding now enable a 176×144 -pixel resolution color video sequence at 15 fps (which requires about 4.5 Mbps to be transmitted in the uncompressed form) to be compressed to about 32–64 kbps while still maintaining adequate viewing quality. The amount of compression that can be achieved is strongly dependent on the content in the video sequence. Video sequences with low motion can be usually compressed more efficiently than video sequences with high motion.

Current second-generation wireless systems provide data rates of only about 9.6–13 kbps. This amount of bandwidth is not enough for acceptable quality videocommunications. Advances in wireless technology and increased spectrum availability have led to the development of third-generation (3G) wireless systems, which provide bandwidths of ≤ 384 kbps outdoors and ≤ 2 Mbps indoors. With this increased bandwidth availability, wireless videocommunications becomes possible. In fact, the first widely deployed mobile wireless videocommunication service was started recently in Japan [1]. This service, called *Freedom of Mobile multimedia Access (FOMA)*, is based on the International Telecommunications Union (ITU)'s International Mobile Telephony (IMT) 2000 3G mobile communication standard. FOMA provides a 64-kbps circuit-switched wireless connection for videoconferencing and a 384-kbps downlink packet-switched wireless connection for streaming video.

A concern while transmitting compressed video data over wireless channels is that the wireless channel is a noisy channel and error bursts are commonly encountered on it because of multipath fading. The effect of channel errors on compressed video data can be deleterious.

Compressed video data are more sensitive to channel interference because of the absence of redundancy in the data. When the video bitstreams get corrupted on the wireless channel, predictive coding causes errors in the reconstructed video to propagate in time to future frames of video, and the variable-length codewords cause the decoder to easily lose synchronization with the encoder in the presence of bit errors. The end result is that the received video soon becomes unusable. Hence it becomes important that a good transport mechanism or protocol, one that provides adequate error protection to the compressed video bit stream, be used while transmitting the video data. Techniques such as forward error correction (FEC) channel coding and/or Automatic Repeat reQuest (ARQ) [2] are usually used for error protection when transporting video data over wireless channels. These techniques introduce redundancy in the transmitted data, thereby giving up some coding efficiency gains achieved by video compression. They also introduce additional delays in the system. In practice, depending on the bandwidth and delay constraints of the system, channel coding can be used to provide only a certain level of error protection to the video bit stream and it becomes necessary for the video decoder to accept some level of errors in the bit stream. Thus, it becomes essential to use error resilience techniques in the video coding scheme so that the video decoder performs satisfactorily in the presence of these errors.

Another challenge faced in wireless videocommunications is that compression and decompression of video and audio data are computationally very complex. Therefore, the processors used in the mobile phones must have high performance—they must be fast enough to play out and/or encode video in real time. Digital signal processors (DSPs) and application-specific integrated circuits (ASICs) are well suited for this task. The processors must also have low power consumption to avoid excessive battery drain and they must also be small enough to fit into compact form factors of mobile phones. Progress in microelectronics has enabled processors to satisfy these conflicting requirements. Note that the power consumption of the displays used to view the video also becomes important and it also needs to be low enough.

International standardization has also played an equally important part in facilitating wireless videocommunications. Standardization of video compression algorithms and communication systems and protocols allow devices from different manufacturers to interoperate—this brings economies of scale and mass production of equipment into picture, thereby facilitating cost-effective services.

In this article, we will focus on describing the relevant international standards that have made wireless videocommunications possible. We will cover standards that specify both the video compression as well as the *systems* for wireless videocommunications. In the next section, we start off by providing an overview of wireless videocommunication systems. We describe three categories of wireless videocommunication systems: messaging video systems, streaming video systems, and conferencing video systems. Wireless videocommunication

systems are actually wireless multimedia communication systems since video is usually transmitted along with speech, audio, other multimedia data such as still pictures and documents, and control signals. In order to design a good videocommunication system, it is important to understand the interplay of video with the other components in the system. Therefore, we also provide an overview of the various components of a wireless multimedia system. The overviews provided in Section 2 will help in understanding why the various parts of wireless multimedia communication standards are required when we explain the standards in a later section. In Section 3, we talk about the Motion Pictures Experts Group (MPEG)-4 video compression standard [3]. MPEG-4 has been standardized by the International Standards Organization (ISO)/International Electrotechnical Commission (IEC). The MPEG-4 video coding standard caters to a wide range of multimedia applications covering a variety of storage media and transmission channels. We describe only those parts of the video coding standard that are suited for mobile wireless communications—this subset of the MPEG-4 video coding standard is called the *Simple Profile*. In Section 4, we describe systems standards specified by the Third Generation Partnership Project (3GPP) for messaging, streaming, and conferencing over 3G wireless networks. We conclude the article with discussions in Section 5.

2. OVERVIEW

There are basically three categories of wireless videocommunication systems: messaging video systems, streaming video systems, and conferencing video systems. One of the main factors that separates these three systems is the amount of playout delay in the receiver. Playout delay is the amount of time between the reception of video data in receiver and the playout of the received video data in the receiver. The playout delay determines whether a high-delay or a low-delay wireless connection is required. Another factor that separates these systems is whether both the video encoder and decoder or only the video decoder is used in the mobile phone—this determines whether a two-way or a one-way wireless video connection is required.

Figure 1 shows the block diagrams of the three wireless videocommunication systems. In *messaging video systems* (see Fig. 1a), a mobile phone wishing to send a video message (e.g., a vacation video clip) first creates the video message by capturing and encoding the video. It then uploads the complete video message onto a *multimedia messaging service center* (MMSC) along with the address of the mobile phone to which the video message is directed to. The mmsc then notifies the recipient mobile phone of the video message that has been sent to it. The recipient mobile phone then downloads the whole video message before playing it out. Video email is a variation of the messaging scheme explained above. In *video email*, the recipient mobile phone polls the email server to see if it has any email. If there is an email on the server, the mobile phone downloads it fully before playing it out. The playout

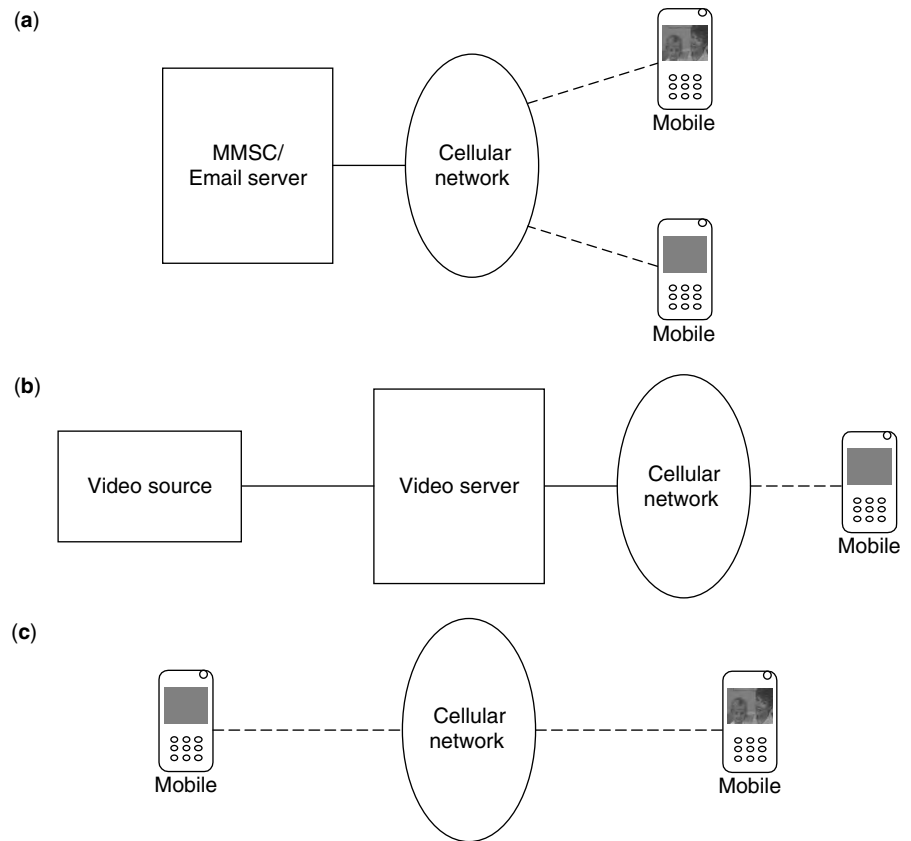

Figure 1. Three basic categories of wireless video systems: (a) messaging systems; (b) streaming systems; (c) conferencing systems. A solid line indicates a wireline connection and a dashed line indicates a wireless connection.

delay in the case of messaging video systems is the time taken to download the entire video message. Note that this playout delay may not be visible to the end user, since the downloading could be occurring in the background and the end user could be notified of the message only when the download is complete. Because of their download-and-play nature, it is not necessary for video messaging systems to have a low-delay connection. Also, the video encoder is not required if the mobile phone wants to have the capability of only receiving video messages.

In *streaming video systems* (see Fig. 1b), the video data received from the video server are buffered for a small amount of time (e.g., ~ 3 s) before being played out. This small buffer absorbs the delay jitters experienced by the video data sent on the wireless channel. The end result is that even if there is delay variation on the wireless channel, the video playout will still be smooth without any breakups. The playout delay in the case of streaming video systems is equal to the initial buffering delay. Note that streaming video systems require a connection that has a delay less than the initial buffering delay in order to have a smooth playout without any breaks. The streaming video data is sent in only one direction—from the video server to the mobile phone. In streaming video systems, a video encoder is not required on the mobile phone. The streaming video data can come from prestored video clips on the server, or they can come from live feeds of news and entertainment events. Note that the video is distributed from the source location to the video servers using a content distribution network, which is typically a wireline network.

Conferencing video systems (see Fig. 1c), which are used mainly for videoconferencing, have very strict delay requirements. The end-to-end delay must be less than 150 ms (though somewhat higher delays might still be acceptable) for the videoconference to be natural. Hence the video data that are received is played out as soon as possible. Also because of the two-way nature of the videoconference, videoconferencing systems require both the video encoder and decoder, and a two-way wireless channel for simultaneously transmitting and receiving the video data.

It is important to note that Fig. 1 illustrates wireless systems, but not wireless applications. In many cases, wireless applications can run on one or more of the wireless systems shown in Fig. 1. For example, a streaming video player *application* can be built on top of a conferencing video system or a streaming video system. The behavior of the streaming video player application will be different on the streaming and the conferencing video system. If the streaming video player application is built on top of a conferencing video system, since there is a very low-delay connection, the streamed video can be played out sooner. The uplink wireless channel (from the mobile phone to the cellular network) will remain unused in this case.

In each of three wireless video systems, video is usually transmitted along with speech/audio and other multimedia data such as images and documents. Therefore the mobile phone used for wireless videocommunications consists of various other components as shown in Fig. 2. The video codec, the audio codec, and the multimedia data blocks process (compress/decompress)

Figure 2. Components of a general wireless multimedia phone.

the video, audio, and multimedia data used in the multimedia communication session. In addition to these blocks, we have two other important blocks: control and multiplex–demultiplex–synchronization (MDS) blocks. The control block is used to initiate and teardown the multimedia communication session. It is also used to decide the audio and video compression methods to use and the data rates to use. The MDS block is used to combine the audio, video, multimedia data, and control signals into a single stream before transmission on the wireless network. In the receiver, it is used to demultiplex the received stream to obtain the audio, video, multimedia data, and control signals which are then passed on to their respective processing blocks. The MDS block is also used to synchronize and schedule the presentation of audio, video and other multimedia data.

In the next section, we describe the video codec block and in Section 4, we will look at the various manifestations of Fig. 2 as applied to messaging, streaming, and conferencing systems standards.

3. MPEG-4 SIMPLE PROFILE VIDEO COMPRESSION¹

The *Simple Profile* of the MPEG-4 video standard [3] uses compression techniques similar to H.263 [5], with

¹This section and the figures appearing in this section have been taken from Ref. 4 with some modifications

Figure 3. MPEG-4 simple profile includes error resilience tools for wireless applications. The core of MPEG-4 simple profile is the H.263 coder. Resynchronization markers, header extension code (HEC), data partitioning, and reversible VLCs provide error resilience support. From Fig. 4 of [4]. © 2000 IEEE with permission.

some additional tools for error detection and recovery. The scope of MPEG-4 simple profile is schematically shown in Fig. 3. As in H.263, video is encoded using a hybrid block motion compensation (BMC)/discrete-cosine transform (DCT) technique. Figure 4 illustrates a standard hybrid BMC/DCT video coder configuration. Pictures are coded in either *intraframe* (INTRA) or *interframe* (INTER) mode, and are called *I frames* or *P frames*, respectively. For intracoded I frames, the video image is encoded without any relation to the previous image, whereas for intercoded P frames, the current image is predicted from the previous reconstructed image using BMC, and the difference between the current image and the predicted image (referred to as the *residual image*) is encoded.

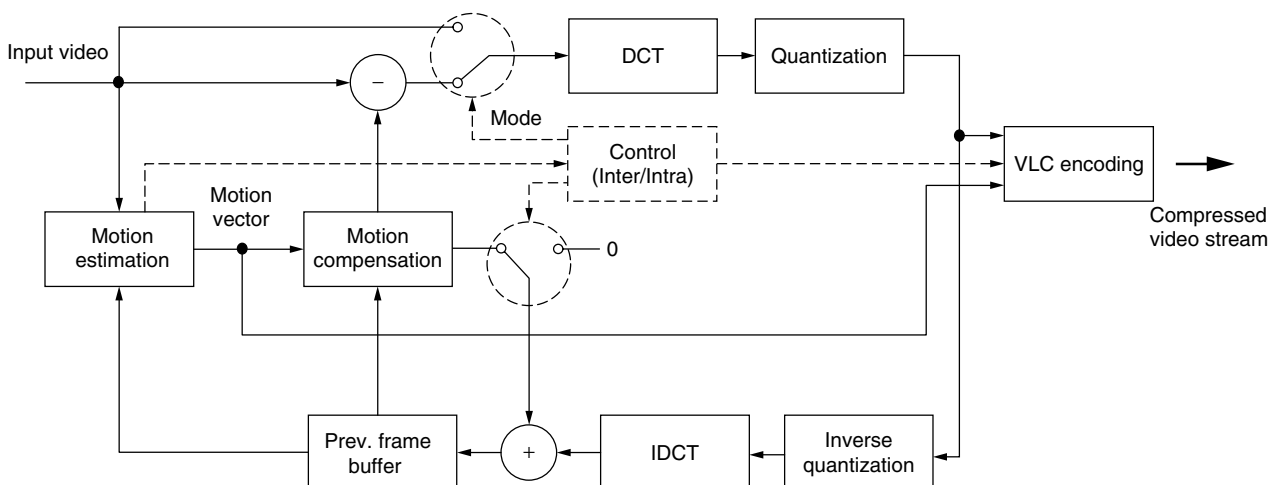

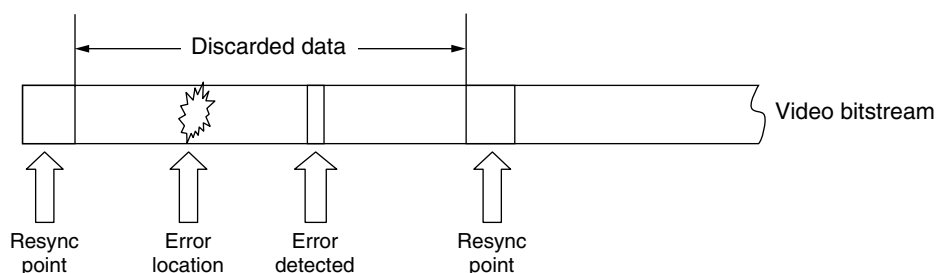

Figure 4. A standard videocoder based on block motion compensation and DCT. From Fig. 5 of [4]. © 2000 IEEE with permission

The basic unit of information which is operated on is called a macroblock and is the data (both luminance and chrominance) corresponding to a block of 16×16 pixels. Motion information, in the form of motion vectors, is calculated for each macroblock in a P frame. MPEG-4 allows the motion vectors to have half-pixel resolution and also allows for four motion vectors per macroblock. Note that individual macroblocks within a P frame can be coded in INTRA mode. This is typically done if BMC does not give a good prediction for that macroblock. All macroblocks must also be INTRA-refreshed periodically to avoid the accumulation of numerical errors, but the INTRA refresh can be implemented asynchronously among macroblocks.

Depending on the mode of coding (INTER or INTRA) used, the macroblocks of either the image or the residual image are split into blocks of size 8×8 , which are then transformed using the DCT. The resulting DCT coefficients are quantized, run-length-encoded, and finally variable-length-coded (VLC) before transmission. Since residual image blocks often have very few nonzero quantized DCT coefficients, this method of coding achieves efficient compression. For INTER-coded macroblocks, motion information is also transmitted. Since a significant amount of correlation exists between neighboring macroblocks' motion vectors, the motion vectors are themselves predicted from already transmitted motion vectors, and the motion vector prediction error is encoded. The motion vector prediction error and the mode information are also variable-length-coded before transmission to achieve efficient compression. In the decoder, the process described above is reversed to reconstruct the video signal. Each video frame is also reconstructed in the encoder, to mimic the decoder, and to use for motion estimation of the next frame.

Because of the use of VLC, compressed video bit streams are particularly sensitive to channel errors. In VLC, the boundary between codewords is implicit. Transmission errors typically lead to an incorrect number of bits being used in VLC decoding, causing loss of synchronization with the encoder. Also, because of VLC, the location in the bit stream where the decoder detects an error is not the same as the location where the error has actually occurred. This is illustrated in Fig. 5. Once an error is detected, all the data between the resynchronization points are typically discarded. The error resilience tools in MPEG-4 simple profile basically help in minimizing the amount of data that has to be discarded whenever errors are detected.

Figure 5. At the decoder, it is seldom possible to detect the error at the actual error occurrence location. From Fig. 6 of [4]. © 2000 IEEE with permission.

The error resilience tools included in the *simple* profile to increase the error robustness are

- Resynchronization markers
- Data partitioning
- Header extension codes (HECs)
- Reversible variable-length codes (RVLCs)

In addition to these tools, error concealment [6] should be implemented in the decoder. Also, the encoder can be implemented to limit error propagation using an adaptive INTRA refresh technique [7].

3.1. Resynchronization Markers

As mentioned earlier, a video decoder that is decoding a corrupted bit stream typically loses synchronization with the encoder due to the use of variable-length codes. MPEG-4 adopted a resynchronization strategy referred to as the "video packet" approach. Packetization allows the receiver to resynchronize with the transmitter when a burst of transmission errors corrupts too much data in an individual packet. A video packet consists of a resynchronization marker, a video packet header, and macroblock data, as shown in Fig. 6. The resynchronization marker is a unique code, consisting of a sequence of zero bits followed by a 1-bit, that cannot be emulated by the variable-length codes used in MPEG-4. Whenever an error is detected in the bit stream, the video decoder jumps to the next resynchronization marker to establish synchronization with the encoder. The video packet header contains information that helps in restarting the decoding process, such as the absolute macroblock number of the first macroblock in the video packet and the initial quantization parameter used to quantize the DCT coefficients in the packet. A third field, labeled HEC, is discussed in Section 3.4. The macroblock data part of the video packet consists of the motion vectors, DCT coefficients, and mode information for the macroblocks contained in the video packet.

Resync marker	MB number	Quant	HEC	Macroblock data
---------------	-----------	-------	-----	-----------------

Figure 6. Resynchronization markers help in localizing the effect of errors to an MPEG-4 video packet. The header of each video packet contains all the necessary information to decode the macroblock data in the packet. From Fig. 7 of [4]. © 2000 IEEE. with permission.

The predictive encoding methods are modified so that there is no data dependency between the video packets of a frame. Each video packet can be independently decoded irrespective of whether the other video packets of the frame are received correctly. A video packet always starts at a macroblock boundary. The exact size of a video packet is not fixed by the MPEG-4 standard (the standard does specify the maximum size that a video packet can take); however, it is recommended that the size of the video packets (and hence the spacing between resynchronization markers) be approximately equal.

3.2. Data Partitioning

The data partitioning mode of MPEG-4 partitions the macroblock data within a video packet as shown in Fig. 7. For I frames, the first part contains the coding mode and six dc DCT coefficients for each macroblock (4 for luminance and 2 for chrominance) in the video packet, followed by a dc_marker (DCM) to denote the end of the first part, as shown in Fig. 7a. (Note that the zeroeth DCT coefficient is called the *dc* DCT coefficient, the remaining 63 DCT coefficients are called *ac* coefficients.) The second part contains the *ac* coefficients. The DCM is a 19-bit marker whose value is 110 1011 0000 0000 0001. If only the *ac* coefficients are lost, the *dc* values can be used to partially reconstruct the blocks. For P frames, the macroblock data is partitioned into a motion part and a texture part (DCT coefficients) separated by a unique motion_marker (MM), as shown in Fig. 7b. All the syntactic elements of the video packet that are required to decode motion related information are placed

in the motion partition and all the remaining syntactic elements that relate to the DCT data are placed in the texture partition. The MM indicates to the decoder the end of the motion information and the beginning of the DCT information. The MM is a 17-bit marker whose value is 1 1111 0000 0000 0001. If only the texture information is lost, data partitioning allows the use of motion information to conceal errors in a more effective manner. Data partitioning thus provides a mechanism to recover more data from a corrupted video packet.

3.3. Reversible Variable-Length Codes (RVLCs)

Reversible VLCs can be used with data partitioning to recover more DCT data from a corrupted texture partition. Reversible VLCs are designed such that they can be decoded both in the forward and the backward direction. Figure 8 illustrates the steps involved in two-way decoding of RVLCs in the presence of errors. While decoding the bit stream in the forward direction, if the decoder detects an error, it can jump to the next resynchronization marker and start decoding the bit stream in the backward direction until it encounters an error. Based on the two error locations, the decoder can recover some of the data that would have otherwise been discarded. Because the error may not be detected as soon as it occurs, the decoder may conservatively discard additional bits around the corrupted region. Note that if RVLCs were not used, more data in the texture part of the video packet would have to be discarded. RVLCs thus enable the decoder to better isolate the error location in the bit stream. Note that RVLC can be used only when data partitioning is enabled.

3.4. Header Extension Code (HEC)

Important information that remains constant over a video frame, such as the spatial dimensions of the video data, the timestamps associated with the decoding and the presentation of these video data, and the type of the current frame (INTER coded/INTRA coded), are transmitted in the header at the beginning of the video frame data. If some of this information is corrupted due to channel errors, the decoder has no other recourse but to discard all the information belonging to the current

Figure 7. MPEG-4 data partitioned video packet for (a) I frames and (b) P frames. Data partitioning uses additional markers (DCM and MM) and puts the most important information in the first partition of video packet, for better error concealment. From Fig. 8 of [4]. © 2000 IEEE with permission.

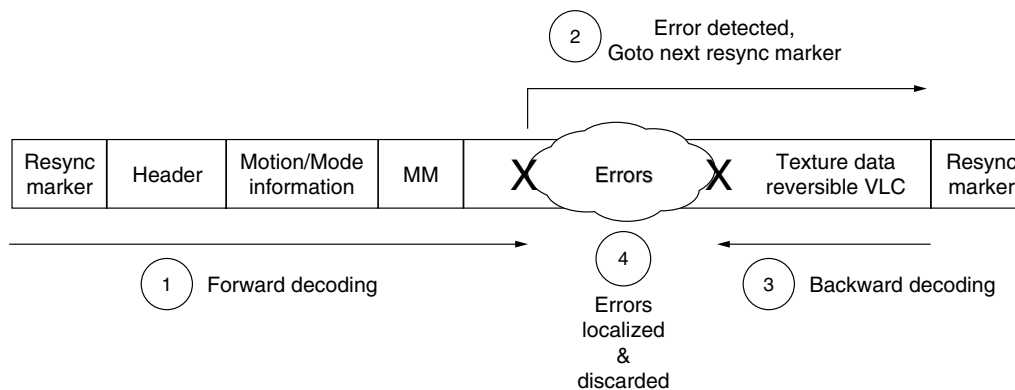

Figure 8. Reversible VLCs can be parsed in both the forward and backward directions, making it possible to recover more DCT data from a corrupted texture partition. From Fig. 9 of [4]. © 2000 IEEE with permission.

video frame. In order to reduce the sensitivity of this data, a 1-bit field called HEC is used in the video packet header. When HEC is set, the important header information that describes the video frame is repeated in the bits following the HEC. This duplicate information can be used to verify and correct the header information of the video frame. The use of HEC significantly reduces the number of discarded video frames and helps achieve a higher overall decoded video quality.

3.5. Error Concealment

The MPEG-4 standard does not specify what action the decoder should take when an error is detected. Several error concealment techniques have been developed based on temporal, spatial, or frequency-domain prediction of the lost data [6]. The simplest temporal concealment technique is macroblock copy. Under this procedure, corrupted macroblocks are replaced with collocated macroblocks from the previous frame. In practice this technique works quite satisfactorily when the amount of motion in video sequences is low, such as the head and shoulder video sequence type that arises in videoconferencing. More sophisticated temporal concealment techniques use the motion vector of the macroblock to copy the motion compensated macroblock from the previous frame. Sometimes the motion vector is available when data partitioning is used. In cases where the motion vector of the macroblock is lost, it is estimated from the motion vector of the neighboring macroblocks. However, temporal concealment cannot be used for the first frame (which is an I frame), and may yield poor results for intracoded macroblocks or areas of high motion. In such cases spatial domain error concealment techniques, wherein lost blocks are interpolated from correctly received neighboring blocks in the video frame, have to be used. Concealment in the spatial domain typically involves more computation because of the use of pixel-domain interpolation. In some cases, frequency-domain interpolation may be more convenient, by estimating the dc value and possibly some low-order ac DCT coefficients.

3.6. Adaptive INTRA Refresh (AIR)

AIR is a standard-compatible encoder technique for limiting error propagation by using nonpredictive INTRA coding [7]. INTRA refresh forcefully encodes some macroblocks in INTRA mode to flush out possible errors. INTRA refresh is very effective in stopping the propagation of errors, but it comes at the cost of a large overhead; coding a macroblock in INTRA mode typically requires many more bits than coding in INTER mode. Hence the INTRA refresh technique has to be used judiciously.

AIR adaptively performs INTRA refresh based on the motion in the scene. For areas with low motion, simple temporal error concealment works quite effectively. Since the high motion areas can propagate errors to many macroblocks, any persistent error in the high motion area becomes very noticeable. The AIR technique of MPEG-4 INTRA refreshes the motion areas more frequently, thereby allowing the possibly corrupted high motion areas to recover quickly from errors.

4. WIRELESS VIDEOCOMMUNICATION SYSTEM STANDARDS

In this section we briefly describe the wireless videocommunication system standards recommended by 3GPP for messaging, streaming, and conferencing. The standards are Multimedia Messaging Services (MMS) standard [8] for messaging, the Real-time Streaming Protocol (RTSP) standard [9,10] for streaming, the Session Initiation Protocol (SIP) standard [11,12] for videoconferencing over packet-switched networks, and the 3G-324 standard [13] for videoconferencing over circuit-switched networks.

It is useful to understand the characteristics of the network types used for these standards first before reading about the standards. The MMS, RTSP, and SIP standards are used over packet-switched networks whereas the 3G-324 standard is used over circuit-switched networks. Circuit-switched networks allocate a dedicated amount of bandwidth to the connection and hence they provide a predictable-delay connection. On the other hand, on packet-switched networks, data is packetized and transmitted over shared bandwidth and thus a predictable timing of data delivery cannot be guaranteed. The types of channel impairments observed on these two types of networks are different. On circuit-switched networks, the transmission errors experienced are in the form of bit errors, whereas on packet-switched networks, the transmission errors experienced are in the form of packet losses. On packet-switched networks, the predominantly used network layer protocol is the Internet Protocol (IP). There are two transport layer protocols developed for use with IP: the Transmission Control Protocol (TCP) and the User Datagram Protocol (UDP). TCP provides a reliable point-to-point service for delivery of packet information in proper sequence, whereas UDP simply provides a service for delivering packets to the destination without guarantee. TCP uses retransmission of lost packets to guarantee delivery. TCP is found to be inappropriate for real-time transport of audio video information because retransmissions may result in indeterminate delays leading to discernible distortions and gaps in the real-time playout of the audio/videostreams. In contrast, UDP does not have the problem of indeterminate delays because it does not use retransmission. However, the problem in using UDP for transmitting media is that UDP does not provide sequence numbers to transmitted packets. Hence UDP packets can get delivered out-of-order and packet loss might go undetected.

Before proceeding ahead in this section, it is also useful to revisit Fig. 2 and Section 2. All the standards follow the overall architecture of Fig. 2. They all differ in the type of control and multiplex–demultiplex–synchronization blocks they use.

4.1. Multimedia Messaging Services (MMS) Standard

Figure 9 shows the MMS [8] protocol stack for multimedia messaging over wireless IP networks. Each MMS multimedia message consists of a MMS header and an optional MMS body. The MMS header is used for signaling information between the mobile phone and the multimedia messaging service center (MMSC), and the MMS body

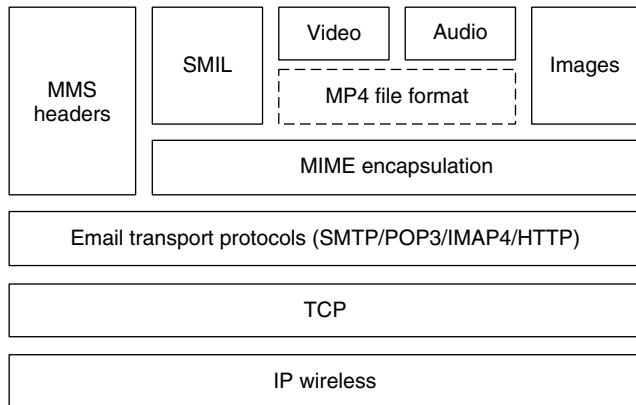

Figure 9. MMS protocol stack for multimedia messaging.

is used to carry the actual multimedia message data. The MMS header includes information on the type of the MMS message, specifically, whether it is a request from the mobile phone to the MMSC, a notification from the MMSC to the mobile phone, or a confirmation response to a request/notification. The header also contains the destination address, the date when the multimedia message was created, the address of the originating mobile phone, the version of the MMS protocol, and more such fields. The MMS body contains the media data and also the layout information, that is, information on where the various media components should be displayed on the screen and also as to when they should be played out and in what order. The presentation layout is specified using the Synchronized Multimedia Integration Language (SMIL) [14]. If audio and video must be played out in a synchronized fashion, then they must be packaged together using the MPEG-4 file format [15] first. The multiple media elements and the SMIL description are combined into a single composite entity using the Multipurpose Internet Mail Extensions (MIME) multipart format [16]. This final MIME encapsulated data forms the MMS body. The whole MMS message (MMS headers and the MMS body) is transmitted using transport protocols used for emails. The email transport protocols are layered on TCP which provides a reliable connection. TCP can be used in messaging systems because messaging systems can tolerate delays. At the receiving end, after the entire MMS message has been received, the mobile phone extracts the multimedia data and the SMIL description from the MIME encapsulated MMS body, and plays out the media according to the presentation information in the SMIL description.

Comparing Fig. 9 to Fig. 2 at a high level, the MMS headers forms the control block and the combination of SMIL, MPEG-4 file format, and MIME forms the multiplex–demultiplex-synchronization block.

4.2. Real-Time Streaming Protocol (RTSP)

The protocol stack for a RTSP-based [9,10] streaming media player is shown in Fig. 10. RTSP specifies a text-based protocol for exchanging control information with the video server. Control messages are used to establish the

Figure 10. RTSP protocol stack for streaming video.

streaming session and to signal the type and format of the media to be used in the streaming session. They are also used for functions such as pausing, fast forwarding, and stopping the media playout. At the beginning of the streaming session, the mobile first sends a RTSP message to the video server specifying the media clip that it wants to watch. This is similar to sending a Webpage address to the Webserver for downloading the Webpage from the Webserver. The video server replies back, providing information on the type and format of the media in the media clip. The Session Description Protocol (SDP) [17] is used to provide this information. The SDP information is enclosed in the response from the server. The mobile phone looks at the enclosed SDP message and decides if it is able to decode the types of media present in the media clip. If it can, it then proceeds and issues a RTSP request to the video server to start streaming the media clip. The video server then starts streaming the media to the mobile phone. The mobile phone typically buffers the media for a short duration of time (e.g., 3 s) before playing them out. At anytime the streaming has to be stopped or paused, the mobile phone sends a RTSP request informing the video server to do so. The RTSP messages are usually transmitted reliably by using TCP.

The media are usually transmitted using UDP for prompt delivery. UDP does not provide timestamp information that is required in the playout of the media. Also as was stated earlier, by using UDP, media packets can get lost and can be delivered out-of-order. Hence the Real-time Transport Protocol (RTP) [18] is used on top of UDP to overcome the shortcomings of UDP. The RTP packet headers contain timestamps and sequence number information. The sequence number enables detection of packet loss and out-of-order packet delivery, and the timestamp provides timing information required in the playout of media.

Comparing Fig. 10 to Fig. 2 at a high level, the combination of RTSP and SDP forms the control block. Synchronization is carried out by RTP. There is no explicit multiplex–demultiplex block since the multiplexing and demultiplexing is carried out at the network level below IP.

4.3. Session Initiation Protocol (SIP)

Figure 11 shows the protocol stack for a SIP-based [11,12] mobile phone for videoconferencing over wireless IP

Figure 11. SIP protocol stack for two-way videoconferencing over packet-switched networks.

networks. As in the case of the RTSP streaming media player, RTP is used for transporting media. The SIP videoconferencing terminal contains both the encoder and the decoder for audio/video, unlike the RTSP streaming media player, which contains only the audio/video decoders.

The SIP protocol is used for signaling call setup and teardown. The SIP protocol can be layered on top of TCP or UDP. SIP also uses textual encoding of control messages. A SIP-based mobile phone wishing to place a call sends a message to the remote end inviting it to a call. Along with the invite message, the mobile phone also sends a SDP message describing the types and formats of media that it can receive and transmit during the call. If the remote end is ready to accept the call, it sends an acknowledgment to the invite. In the acknowledgment, the remote end sends back a SDP message indicating the media types and formats it can receive and transmit. Using the SDP messages, both endpoints can then decide on the media format that each will use for transmission and then start transmitting the media using RTP. Either end can end the call by sending a “Bye” message.

Comparing Fig. 11 to Fig. 2 at a high level, the combination of SIP and SDP forms the control block. Synchronization is carried out by RTP. There is no explicit multiplex–demultiplex block since the multiplexing and demultiplexing is carried out at the network level below IP.

4.4. 3G.324

For videoconferencing over circuit-switched wireless networks, 3GPP specifies the use of the 3G-324 standard [13]. The 3G-324 standard is based on the ITU standard for circuit-switched multimedia communications—H.324 [19]. The protocol stack for a 3G-324 videoconferencing terminal is shown in Fig. 12. Video, audio,

Figure 12. 3G.324 protocol stack for two-way videoconferencing over circuit-switched networks.

and the control information are sent on distinct logical channels. The H.245 standard [20] is used to negotiate the media to be used in the call and also to set up the logical channels for the media. The H.223 standard [21] determines the way in which the logical channels are mixed into a single bit stream before transmission over the wireless channel. The H.223 standard was originally designed for operation over the benign public switched telephone networks. H.223 was later extended for operation over error-prone wireless channels. H.223 consists of two layers: the adaptation layer and multiplex layer. The adaptation layer allows for the use of both FEC and ARQ to protect the media being transmitted. This error protection is in addition to what might be provided by the wireless network. The multiplex layer is responsible for multiplexing the various logical channels into a single bit stream.

Comparing Fig. 12 to Fig. 2 at a high level, H.245 forms the control block and H.223 forms the multiplex–demultiplex–synchronization block.

5. DISCUSSION

In this article we provided an overview of wireless video communications and described the various international standards that have made it possible. In addition to video compression, error resilience techniques for video and efficient mechanisms for video transport are important in wireless video communications. We discussed the *Simple Profile* of MPEG-4 video coding standard which introduces several error resilience tools aimed at containing the effect of transmission errors in the video bit stream. In practice, video is usually transmitted along with speech, audio, multimedia data such as images and documents, and control signals to form a complete multimedia communication system. It is important to understand the interplay of video with the other components of the multimedia communication system. So we also provided an overview of the following systems standards that have been recommended by 3GPP for use over third generation wireless networks: MMS for multimedia messaging, RTSP for streaming, SIP for videoconferencing over packet-switched wireless networks, and 3G.324 for videoconferencing over circuit-switched wireless networks. It should be noted that though these standards were specifically described for use on wireless networks, many of them can be used and are being used on wireline networks too.

In addition to the standards described in this article, there are other video coding standards and proprietary techniques that can/will be used on wireless networks. ITU has also extended the H.263 to provide support for error resilience. In 3GPP standards, baseline H.263 is the mandatory video coder that has to be supported. Both MPEG-4 and the extensions to H.263 (called H.263++) are optional. The first commercial wireless video deployment—FOMA [1]—uses MPEG-4. For wireless streaming applications, proprietary video compression standards such as Quicktime, RealVideo and Microsoft Windows Media Video might also be used because of the wide availability of existing content in those formats on the World Wide Web.

Wireless videocommunications is a relatively new field, and there is a lot of ongoing research activity for improving the overall video quality. Techniques such as joint-source channel coding, where the amount of bits allocated to source coding and channel coding are adaptively varied according to channel conditions, and unequal error protection (UEP), where the level of error protection is varied per the importance of the data, are being studied. Layered video coding, where the video is split into a base layer and several enhancement layers that provide incremental quality improvement over the layers below them, can be used in conjunction with UEP with the base layer being protected the most. Low-complexity (and hence low-power) video compression is another important field of research. In addition to research in video compression, research activities in the fields of low-power semiconductors and displays, wireless communications and networking, are all simultaneously enabling wireless video to become a compelling application on mobile phones.

BIOGRAPHY

Madhukar Budagavi received the B.E. degree (first class with distinction) in electronics and communications engineering from the Regional Engineering College, Trichy, India, in 1991, and the M.Sc.(Engg.) degree in electrical engineering from Indian Institute of Science, Bangalore, India, in 1993, and the Ph.D. degree in electrical engineering from Texas A&M University, College station, Texas (USA), in 1998.

From 1993 to 1995, he was first a Software Engineer and then a Senior Software Engineer in Motorola India Electronics Ltd., primarily developing DSP software and algorithms for the Motorola DSP chips. Since 1998, he has been a Member of Technical Staff with the Texas Instruments DSP Solutions R&D center, working on MPEG-4 and protocols for wireless videocommunications. His research interests include video coding, speech coding, and wireless and Internet multimedia communications.

1. INTRODUCTION

Wireless packet data is defined as the transfer of information over wireless links that are shared dynamically

by multiple users without dedicating wireless resources to individual users during periods of inactivity.

In traditional circuit-mode cellular voice services, radio resources (e.g., frequencies, time slots, or codes) are assigned exclusively to a single user for the duration of a call. As a result, resources remain assigned during periods of inactivity. Circuit mode voice service is fairly wasteful of network resources. Studies of conversational patterns, for example, indicate that the amount of time speakers actually speak accounts for only 40–50% of the duration of the call. The remaining time is consumed by pauses in conversation. Due to the bursty nature of data transmissions, periods of activity for data services users tend to be much lower (e.g., 10–15%). Under these traffic assumptions, packet-mode operation allows much more efficient utilization of radio resources than circuit mode. In packet mode, a stream of bits is broken down into smaller units, or packets, which are individually transferred through the network. The communication resource may be dynamically shared by multiple users at any given time. Circuit mode operation wastes resources during periods of inactivity. With packet mode operation, the communication resource is shared by multiple users, and an active user can take advantage of the inactive periods of other users.

The most commonly used electromagnetic wireless access media include radio frequency (RF) waves and lightwaves. When the frequency is below 1 THz (terahertz), the electromagnetic waves are referred to as RF, and above 1 THz, they are called lightwaves. The most commonly used RF band for wireless communications is from 800 MHz to 100 GHz. The most commonly used lightwave wavelengths for wireless communications are infrared, with wavelengths ranging from 870 to 900 nm. The range of RF spectrum less than 800 MHz has been used by radio, TV broadcast, and transportation. Generally speaking, the higher the frequency, the more directional the propagation of electromagnetic waves and the shorter the range of the signal. At one extreme, lightwaves are usually limited to short range line-of-sight communications, such as indoor wireless and point-to-point inter-building communications. At the other extreme, RF spectrum at about 1 or 2 GHz is widely used for cellular wireless communications over large coverage areas because this spectrum does not experience interference from other services and it also provides good coverage in both rural and urban areas without any line-of-sight requirements. As a result, multiple users at different locations can easily share the radio channel. This is well suited for point-to-multipoint, broadcast or multicast communication.

The transmission characteristics of wireless channels are random, time-varying, and difficult to predict. Consequently, the data rate that can be achieved varies depending on the prevailing channel quality. Therefore, it is important to employ link adaptation algorithms that can measure the channel and quickly adapt to the physical-layer parameters in order to maximize the throughput under the prevailing channel conditions. Furthermore, wireless packet data channels are shared by multiple users, and the user throughput performance or system capacity is strongly dependent on the resource allocation

and scheduling schemes employed. In general, resource allocation, scheduling, and link adaptation schemes should be carefully designed in order to maximize the user throughput and/or the system capacity.

Portability and mobility are two major advantages of wireless packet data. Wireless local area networks (WLANs), for example, IEEE 802.11 [1], were originally conceived to serve the purpose of portability within the office. Most lightwave-based wireless packet data services are also used to avoid wiring. Unlike WLANs, cellular packet data systems typically support lower data rates but provide wide-area coverage and support mobility. Third Generation (3G) networks will also be able to coarsely track user locations and provide location based services. Cellular packet data networks have evolved from cellular voice networks, and have inherited mobility support from voice networks. WLANs, however, were conceived in order to provide Ethernet-like connectivity without wires and have focused more on providing wireless access to the wired network. The support of mobility is a task left to Internet Engineering Task Force (IETF) protocols such as mobile IP. The distinction between cellular packet data networks and WLANs may blur and finally disappear as the convergence of the two types of networks becomes more evident.

The main purpose of wireless packet data is to connect mobile users to the fixed network and to connect mobile users to each other. In the wired network, packets generated by end users are directly forwarded to the destination if the destination is within the same local area network (LAN). Otherwise, packets are forwarded through a predetermined route or are routed hop by hop to the final destination. Wireless access usually refers to the “last mile” connection of the end-user devices to the network. Wireless access can be provided using a traditional cellular approach or alternatively, using wireless LANs. The cellular approach assumes that a mobile terminal communicates with a base station over a radio link. The base stations are connected to each other and to the Internet through a wired network. The wireless LAN approach assumes a more ad hoc structure, in which terminals may communicate with each other directly without the help of a base station or wired network. However, if a wireless terminal needs access to the Internet, the wireless LAN should provide an access point that is connected to the wired network. The cellular network model and ad hoc wireless LAN model are illustrated in Fig. 1.

2. GENERIC WIRELESS PACKET DATA SYSTEM ARCHITECTURE

Figure 2 shows a generic wireless packet data system protocol stack. Layer 1 represents the physical layer, which is responsible for radio signal transmission and reception. Layer 2 includes the medium access control (MAC) and radio link control (RLC) layers. The MAC layer allocates airlink resources to mobiles, thus allowing them to share the wireless link. The RLC protocol provides reliable in-sequence packet delivery when configured to operate in an acknowledged mode. Layer 3 provides

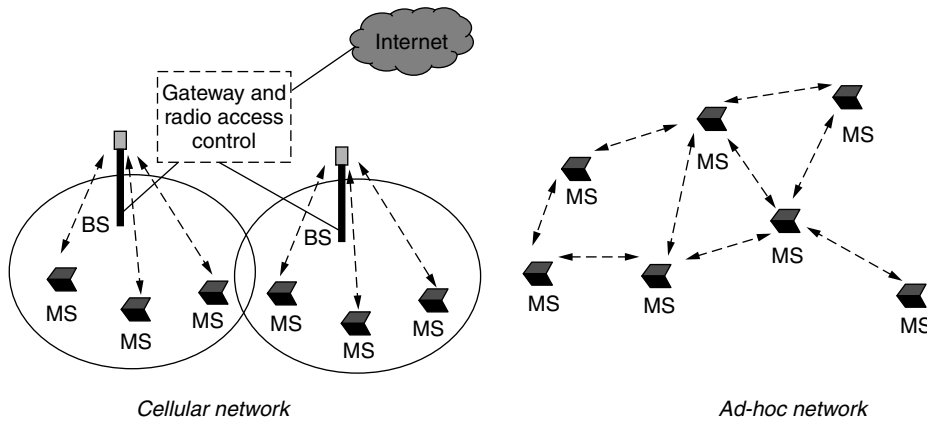

Figure 1. Two basic network connection structures. In cellular networks, mobile stations (MSs) are connected to the base station (BS) via a wireless link. The BS is connected to a gateway that controls the data transfer between the radio access network and the rest of the wired network. In ad hoc networks, MSs are connected to each other directly through radio or infrared links. A terminal can route data to other terminals with which radio links can be established so that terminals that are a few hops away can communicate with each other.

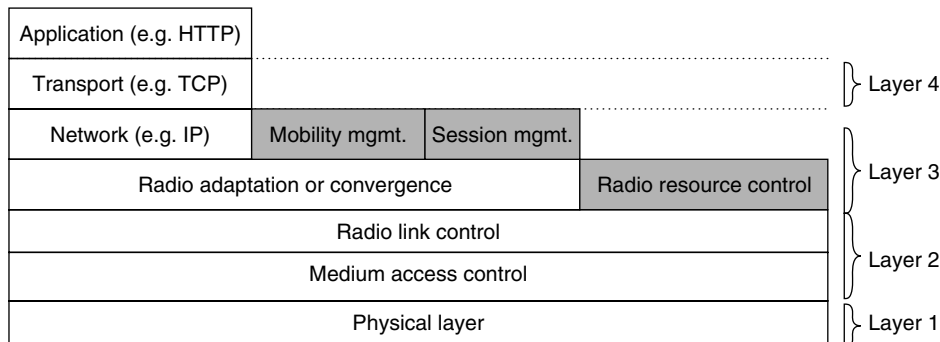

Figure 2. Protocol stack for wireless packet data (signaling plane protocols are shaded).

functions that connect radio access networks to the wired network, such as radio resource control, mobility management and routing within and beyond the radio access networks. In addition, layer 3 may also perform header and/or payload adaptation. The radio adaptation or convergence sublayer is also referred to as the logical link central (LLC) layer. Ciphering may be performed in layer 2 or in layer 3. Layer 4, the transport layer, provides reliable end-to-end data transfer and end-to-end flow control, if desired. The application layer denotes end user applications (e.g., HTTP for Web browsing).

All four layers of the protocol stack are implemented in mobile stations. On the fixed network side, however, portions of the protocol stack are implemented on different network elements. The choice of how to partition the protocol stack is influenced by technology requirements and/or constraints imposed by legacy systems. In General Packet Radio Service (GPRS) and Universal Mobile Telecommunications System (UMTS) systems, for example (Fig. 3) [2], the base station is responsible for physical-layer functions such as channel coding/decoding, modulation/demodulation, pulse shaping and transmission; MAC, RLC, and some radio resource control functions are in a remote radio network controller, which controls several base stations. The Serving GPRS Support Node (SGSN) and Gateway GPRS Support Node (GGSN) are responsible for session management (i.e., packet data service and context activation, authentication, and charging), mobility management and routing. Any two mobile stations that are served by the same GGSN can communicate with each other directly through the

wired backbone (i.e., network of SGSNs) of the wireless packet data network. In a WLAN configuration, the base station (or access point) includes all user plane protocols up to layer 3. There is no dedicated wired backbone network in this case. Instead, the access point acts like any IP router within the wired network, and IP-based protocols specified by the IETF are used for mobility and session management (mobile IP, AAA (Authentication, Authorization and Accounting) protocols, etc.).

Ideally, wireless packet data systems should provide at least the same services that are currently provided over

Figure 3. UMTS system architecture. A radio network controller (RNC) controls several base stations. Several RNCs are connected to a Serving GPRS Support Node (SGSN). The wired network of SGSNs is referred to as the “backbone” or “core network.” The Gateway GPRS Support Node (GGSN) serves as a gateway between the wired backbone and the Internet or other virtual private networks.

wired networks. In addition, there may be services that are specifically targeted at mobile users. From an application perspective, wireless packet data systems should be able to provide these services with acceptable quality. From a business perspective, it is desirable to provide these services to as many users as possible. These objectives need to be satisfied under constraints on spectrum availability, cost and complexity. Furthermore, services targeted at mobile terminals should be enabled through small and inexpensive terminals with long battery life. These issues pose several challenging problems for wireless packet data system design, as will be discussed later.

3. QUALITY OF SERVICE REQUIREMENTS

Wireless packet data technologies support data transfer services with a wide range of quality of service (QoS) levels. End-to-end QoS requirements (e.g., loss and delay) can be broken down into corresponding requirements on the wireless data network (i.e., user equipment to a wireless gateway node) and on the fixed network. The QoS classes and attributes employed by the wireless data network should span a wide range of possible applications. Because of the limited amount of bandwidth available at the air interface, support of QoS must not involve significant overhead or complexity and should allow efficient utilization of resources.

The third-generation partnership project (3GPP) specifications define four QoS classes [3]:

- *Conversational Class.* The requirements for this class are similar to those for conventional telephony. In order to maintain acceptable quality, there are strict limits on transfer delay and loss rate (1–3%). Furthermore, the time relation between information entities (e.g., speech frames) needs to be preserved.
- *Streaming Class.* Streaming audio and video applications fall into this category. Streaming applications are more tolerant of packet transfer delays than conversational applications. The time relations (variation) between information entities (i.e., samples, packets) within a flow are to be preserved. In addition, loss rates must be low (1–3%).
- *Interactive Class.* Web browsing, database queries and other applications that follow a request/response pattern are considered interactive. Payload content must be preserved (i.e., lossless transfer). In addition, limits are placed on acceptable round-trip delay
- *Background Class.* This class of traffic is delay insensitive (i.e., best effort). Examples include electronic mail (email) and short message service (SMS). This class requires that the payload content be preserved but does not have stringent delay requirements.

Because of signaling and packet transfer delays, airlink error detection and recovery takes time. The stringent delay requirements for voice services, however, do not allow sufficient time for error recovery. Due to advances in speech coding, the rates demanded by voice services are

quite low (<12–16 kbps). The typical approach is to pad transmissions with enough redundancy to allow operation under poor channel conditions. The channel coding is fixed, and no retransmissions are allowed. This error avoidance approach is not well suited to the support of data services. Since the delay requirements for data services are typically more relaxed than voice, error detection and recovery techniques can be used. It is inefficient to use a fixed amount of redundancy independent of the actual delay requirements and the prevailing channel quality. Higher data rates can be supported if error recovery is carried out using an automatic repeat request (ARQ) scheme.

For best-effort data services, the radio link control (RLC) layer typically allows *full recovery* [i.e., service data units (SDUs) are not discarded and there is no limit on the maximum number of retransmissions] and delivers data in sequence to the higher layer. This scheme is best suited to the support of best-effort data services over wireless links, and not to applications such as streaming where the time relation between information entities needs to be preserved. For streaming, a selective ARQ scheme with SDU discard and limited retransmission (i.e., partial recovery) capability can achieve better performance.

4. WIRELESS PACKET DATA TECHNOLOGIES

4.1. Performance Measures

4.1.1. Delay. From the user perspective, it is meaningful to consider measures such as the transfer delay for a speech frame, file, web object or webpage. The air interface is often the largest contributor to “end-to-end delay” perceived at the application layer. A widely used measure of performance for protocol performance in wireless data systems is the SDU delivery delay over the air interface (i.e., delay between peer RLC protocol layers).

The RLC SDU delivery delay may be defined as the time between SDU arrival at the transmitter RLC to in-sequence delivery by the receiver RLC. The RLC SDU delivery serves as a good measure of performance over the air interface for streaming, interactive, and background data services.

For data traffic with varying SDU sizes, a more appropriate measure of performance is the ratio of the SDU delivery delay to SDU size. This is typically known as the *normalized SDU delivery delay*.

SDU delay is a random quantity. Delay jitter (variance) is important when constant delivery rate is required. If the transmission control protocol (TCP) is used for end-to-end error detection and recovery, for example, the delay jitter must be kept as small as possible. This will be elaborated on later. Another metric is delay percentiles, specifying the percentage of transferred packets that experience a delay exceeding a certain value. This is often used in the case when a packet delay exceeds a certain threshold and the packet is dropped.

4.1.2. Throughput. For a given choice of physical-layer parameters (coding, spreading, modulation), an upper bound on the expected user throughput over the air interface is given by $R \cdot (1 - b)$, where R denotes the peak

data rate and b denotes the expected error rate of each RLC packet. Throughput can be improved further when selective hybrid ARQ (i.e., incremental redundancy, which will be discussed later) is employed for radio link control.

There are usually two types of throughput measures mentioned in the literature. One is *user-perceived throughput*, which is usually used as one of the metrics to quantify the quality of service provided to the mobile user. The user-perceived throughput is the individual user's data throughput when the user has data to transmit. Wireless packet data channels are shared by multiple users and the user-perceived throughput computation should additionally account for the queuing time. In the literature, the data rate quoted for the system usually refers to user-perceived throughput. The other type of throughput is *aggregated throughput* or *system throughput*, which is usually used to quantify the system capacity or system load. The aggregated throughput is the amount of bits successfully transmitted per unit time in the whole system that includes all users. User-perceived throughput usually should be used together with system aggregated throughput, because in many cases, system aggregated throughput is proportional to the system loading and the user-perceived throughput decreases when the system loading increases.

4.1.3. Packet Loss and In-Sequence Delivery. Wireless packet data systems typically require in-sequence SDU delivery over the air interface. If selective ARQ is employed, this translates into a requirement on the RLC protocol. Note that in-sequence delivery does not imply lossless data transfer.

SDU loss can occur in one of the following ways:

- Buffer overflow at the transmitter.
- SDU discard at the transmitter if the delivery delay requirements cannot be met.

The loss rate requirement depends on the QoS requirements of the application.

4.1.4. Coverage and Mobility Support. It is desirable to satisfy a minimum throughput or a maximum SDU delivery delay (or normalized SDU delivery delay) for a large fraction (90–95%) of users in the network.

Most cellular data networks allow users to roam over a wide area and attempt to provide an “always on” experience for the end user (i.e., mobility management is handled without significant impact on the service). In addition, for real-time services, handovers should occur seamlessly as a mobile terminal moves from the coverage area of one sector to another. This is achieved by imposing very stringent delay requirements on a handover. Generally speaking, there is a tradeoff between providing high-throughput service and providing large coverage and good mobility support. For example, at the time when this article is written, WLANs provide a data rate as high as 11 Mbps (with future standards targeting rates up to 54 Mbps), but coverage is typically limited to indoor environments with no mobility. On the contrary, the 3G

wireless networks can support only 384 kbps, optimistically, but with almost seamless coverage and mobility support.

4.1.5. Security. Wireless packet data systems must provide safeguards against unauthorized network access and protect users' privacy. This is achieved through security protocols that carry out authentication and ciphering of user data and protect the integrity of control information.

To prevent unauthorized access, users need to be authenticated before they can access the wireless network. This typically involves comparison of a user-provided unique equipment ID number with ID numbers stored and maintained by the network. The network may also ask for a password to check the user's identity.

The content of the user's data, location, identity, and data usage pattern must all be protected. The use of wireless links makes it easier for casual eavesdroppers to infringe on a user's privacy. The objective of the security provided through wireless packet data is to provide security at levels comparable to wireline data service. This requires that user data be encrypted before they are sent over the air. In addition, the network should try to reduce the times that the mobile user sends its unique ID number over the air. This prevents eavesdroppers from deriving a user's location and data usage pattern. Once a user is registered with the network, the network can assign a temporary ID for the user and the temporary ID number can be used for authentication. It should be emphasized that the wireless data networks do not provide end-to-end security. Such security must be provided by the users/applications themselves or IP-based security protocols (e.g., IPSec).

4.1.6. Energy Efficiency. Many mobile terminals are powered by batteries and energy efficiency is quite important. Low mobile terminal power consumption is critical in order to lengthen communication time and to prevent mobile devices from overheating.

The definition of energy efficiency is not as simple as it appears to be. At first glance, energy efficiency can be defined as the amount of energy expended per information bit received. But this definition does not capture the data rate. Generally speaking, the higher the data rate, the higher the amount of energy expended per unit of information bits received. This is due mainly to two effects: (1) the higher data rate implies higher receiver processing requirements and (2) increasing data rate over the air interface requires higher transmission power per bit. According to Shannon theory, the required transmission power is an exponentially increasing function of the supported data rate. If the wireless link is shared by multiple users in certain ways, increasing one user's data rate leads to a higher interference level being experienced by other users. Therefore, the other users need more transmission power to combat the increased interference level. From a system perspective, if multiuser interference is a concern, the higher the aggregated throughput of the system, the higher the energy requirement per information bit. A

good indication of energy efficiency, therefore, is a power consumption function corresponding to the supported data rate.

Reduction of power consumption in wireless packet data involves optimization of all aspects of the system and circuit design, from hardware and software to communication protocols. For example, on the RF portion of a mobile terminal's circuitry, the use of low peak-to-average modulation schemes and nonlinear amplifiers improve amplifier efficiency and saves energy. On the digital logic part of a mobile terminal's circuitry, low-voltage and low-clock-frequency circuits are preferred for power reduction. Integration of the system into a small number of chips is desirable to reduce I/O power consumption. Discontinuous transmission and reception¹ modes that allow the mobile to go idle if there are no data to send or receive are very useful in reducing power consumption. All the power reduction approaches discussed must ensure that they do not compromise performance.

4.2. Technology Methods

4.2.1. Link Adaptation and Incremental Redundancy. Link adaptation is a technique that uses channel quality measurements in order to select the physical-layer parameters such as modulation, coding, and spreading that are needed in order to achieve the highest throughput under delay constraints [4]. The RLC block sizes and physical-layer parameters should be chosen in such a way that blocks can be retransmitted without significant overhead even if the physical-layer parameters used for the initial transmission are different from those used for retransmission.

Incremental redundancy is a technique that can be applied in conjunction with link adaptation in order to achieve higher throughput under a wide range of operating conditions. For each set of physical-layer parameters, a set of puncturing schemes (P1, P2, P3, etc.) achieving the same code rate are defined. All puncturing is carried out on the same rate $1/N$ "mother code." The initial transmission of a block consists of the bits obtained by applying the puncturing scheme P1 (for the chosen physical-layer parameters) to the rate $1/N$ encoded data. On receiving a negative acknowledgment

for the RLC block, additional coded bits (i.e., the output of the rate $1/N$ encoded data punctured with scheme, P2, corresponding to the prevailing set of physical-layer parameters) are transmitted. If all the punctured versions of the encoded data block have been transmitted, the cycle is repeated, starting again with P1. If the receiver does not have sufficient memory for incremental redundancy operation, it can attempt to decode the data by using the information corresponding to just P1, or P2, or P3. This corresponds to the pure link adaptation case. For incremental redundancy operation, the receiver must have sufficient memory in order to store soft information corresponding to RLC blocks that have not yet been decoded successfully. Each time the receiver obtains additional coded bits, it attempts soft-decision decoding using this redundant information in addition to previously stored soft information corresponding to the same RLC block(s).

The individual puncturing schemes are designed to be as disjunctive (or nonoverlapping) as possible in order to achieve good performance with incremental redundancy. In addition, to achieve good performance with pure link adaptation, the puncturing schemes are designed to ensure that the individual schemes (P1, P2, P3) achieve comparable error performance.

4.2.2. Peak Picking Scheduling. In a cellular environment, different users sharing the same airlink will observe different link performance. In addition, the performance observed by each user may vary in time due to changes in interference levels and shadow fading.

Figure 4 shows an idealized plot of logical link control (LLC)-layer efficiency variations as a function of time as link adaptation tracks the changes in link quality.

To increase overall system capacity, a scheduler can dynamically allocate larger portions of airlink resources to those users with high link efficiencies, a technique known as "peak picking." To help understand the role peak picking plays in the design of airlink schedulers, it is helpful to look at two extremes:

- One naive scheduling algorithm is to allocate all network resources to the mobile with the highest link efficiency. Such an algorithm maximizes the total amount of data carried over the airlink. However, such an algorithm is woefully impractical. One problem with such a scheduler is fairness. Using

¹ Discontinuous reception is commonly referred to as "sleep mode."

Figure 4. Peak picking can substantially improve overall system capacity. The curves represent the throughputs that mobile 1 and mobile 2 would receive if they were given all airlink blocks. With peak picking, network operators will be able to generate more revenue from the airlink.

such a scheme, it is possible that one user in the cell is granted all airlink bandwidth, while all other users starve. Such bandwidth starvation can have disastrous effects on the performance of higher-layer protocols, such as TCP. Such starvation can result in frequent TCP retransmissions and TCP connection failures: focusing on maximizing airlink throughput alone may end up causing transmission inefficiency at higher layers. In addition, it is often necessary for the network to periodically schedule transmissions to/from a mobile so that it has current information needed for power control and link adaptation to function properly.

- At the other extreme is simple round-robin scheduling, in which each user is given an equal fraction of airlink blocks. Such a scheduling scheme does not take advantage of peak picking.

Effective schedulers employing peak picking lie somewhere between these two extremes. The design of such schedulers is currently an active area of research.

4.2.3. Header Compression. Wireless data networking technologies are designed to make most efficient use of airlink spectrum. Link adaptation and incremental redundancy techniques are one way of doing this. Another way of increasing link efficiency is to shrink the size of user data packets carried over the wireless data network's airlink. Two additional tools are used for this purpose: packet header compression and packet payload compression.

Each TCP/IP packet contains a 20-byte TCP header and a 20-byte IP header. For small payloads, 40 bytes of overhead is a large price to pay. For this reason, wireless data networks typically employ techniques to compress the headers of each network-layer packet carried over the airlink. Such schemes are based on the packet header compression scheme developed by Van Jacobsen [5]. Taking advantage of the fact that many of the fields in TCP/IP packet change little over the lifetime of a TCP connection, Van Jacobsen's header compression algorithm can reduce the amount of data needed to carry a TCP/IP packet header from 40 to 3 bytes. Similar techniques are also being proposed to reduce the headers used by UDP/IP headers to enable efficient carrying of audio streaming and voice over Internet Protocol (VoIP) applications, which typically have payloads of less than 100 bytes.

Packet payload compression schemes can also increase airlink efficiency. V.42bis data compression is a common

compression scheme used by wireless data networks. V.42bis is based on the string compression algorithm of Ziv–Lempel [6]. V.42bis maps strings appearing in the uncompressed input data to a set of codewords. Both the compressor and decompressor dynamically construct a dictionary mapping codewords to strings. By sending shorter-length codewords over the airlink instead of the longer length strings the codewords represent, V.42bis can achieve favorable compression ratios and make more efficient use of the airlink. V.42bis, however, may be used only over links providing lossless, in-sequence packet delivery.

4.2.4. Mobility Management. Wireless data networks employ several mobility management techniques to give mobile terminals access to the Internet. Some wireless data network technologies leverage the use of mobility management architecture already deployed for the service of circuit-switched traffic (e.g., GPRS/EGPRS, UMTS). Other wireless data technologies (e.g., CDMA2000) have opted instead for mobility management based on mobile IP.

4.2.4.1. Mobility Management in GPRS/EGPRS and UMTS. Figure 5 shows the high-level mobility management architecture employed by GPRS/EGPRS and UMTS networks. In these technologies, each user is assigned a “home” service provider, the provider who bills for their service. Mobiles are also permitted to use networks other than those owned by their home service provider, a process known as “roaming.”

Mobility management in GPRS/EGPRS and UMTS networks uses the following network entities:

- *Visitor Location Register (VLR).* This is a database containing information on the roaming mobiles currently active in a service provider's network. The VLR contains information on the roaming current mobiles' locations, the identities of the mobiles' home service provider, information needed to authenticate users, and the capabilities of roaming mobiles and other information. This database also contains information on roaming circuit-switched customers currently using the service provider's network.
- *Home Location Register (HLR).* Similar to the VLR, this database contains information on all mobiles that receive service from the service provider. This database also contains information on the service provider's circuit-switched customers.

Figure 5. Mobility management architecture employed by GPRS/EGPRS and UMTS networks.

- **GGSN.** The GGSN is a gateway node used to mask the mobility of mobile hosts from Internet applications. All data traffic sent between a mobile host and fixed host are routed via the GGSN. The GGSN collects usage information that can be later used to bill users for wireless data service. A GGSN may access the VLR/HLR to obtain information on mobile capabilities and special features that a user has subscribed to. The GGSN tunnels network layer traffic to the SGSN that a mobile host is currently attached to.
- **SGSN.** The SGSN tracks a mobile as it moves from cell to cell, delivering the network-layer packets it receives from the GGSN. The SGSN may compress the header and payload of the packets it transmits. The SGSN tunnels packets it receives from the mobile host to the GGSN. The SGSN also communicates with the VLR/HLR to retrieve mobile capabilities and update location information and mobile state. The SGSN also collects mobile-specific usage data that can be later used for billing.

Mobility management “procedures” are used to activate or deactivate data service and track mobiles as they move from cell to cell. During each procedure, signaling messages are exchanged between the mobile host and network entities:

- **Attach.** Before being able to transfer data over a wireless data network, a user must “attach.” During the attach procedure, signaling messages are exchanged between the mobile host and the SGSN to identify and authenticate the mobile. Credentials supplied by the mobile may be compared with credentials the SGSN retrieves from the mobile’s HLR. The SGSN updates the mobile’s HLR with its new location. If the state information in the HLR shows that the mobile was attached with another SGSN, the new SGSN informs the old SGSN that the mobile will no longer need service from the old SGSN. The SGSN assigns the mobile a temporary link layer address which will be used to identify the mobile for as long as it remains attached.
- **Detach.** The detach procedure may be initiated by a mobile (called an “explicit detach”), or initiated in response to a lack of routing area update messages (called an “implicit detach”). The detach procedure informs the wireless data network that a mobile is no longer available to send and receive data over the wireless data network. During a detach, the VLR is updated to indicate that the mobile is now idle.
- **Packet Data Protocol (PDP) Context Activation.** PDP context activation makes a mobile “visible” to the public Internet. Signaling messages sent between the mobile and the SGSN identify the type of service that the mobile is requesting. The SGSN may perform optional procedures to determine whether the mobile is allowed access to the type of service it is requesting. If the SGSN determines the context activation should be allowed, it informs a GGSN to create a PDP context for the mobile. Once a PDP context has been created, IP traffic can flow between a mobile and the public Internet.
- **Packet Data Protocol (PDP) Context Deactivation.** PDP context deactivation is used to signal the end of a data session. Once a mobile’s PDP context has been successfully deactivated, the SGSN and GGSN that were serving the mobile are free to assign network resources (memory, link bandwidth, etc.) to other mobiles. At the end of PDP context deactivation, a mobile is no longer reachable from the public internet.
- **Routing Area Update.** To help manage the amount of signaling traffic needed to track a mobile as it moves from cell to cell, contiguous clusters of cells are grouped together to form a “routing area.” Mobiles are required to inform the SGSN any time they begin to receive service in a cell with a new routing area identifier, a process known as a *routing area update*. Routing areas are also used to control the amount of paging traffic that must be generated to deliver traffic to mobiles in standby mode. Paging messages are only sent in those cells belonging to the routing area the mobile was last known to be in. Routing area updates are sent periodically by mobiles in standby mode. If a mobile does not send periodic updates, the network will detach the mobile, freeing up resources for other mobiles.
- **Paging.** Constant reception and decoding of airlink channels drains a mobile’s battery. To increase battery life, during times of inactivity, mobiles enter a “standby mode.” While in standby mode, mobiles periodically decode paging channels to determine whether the network wished to send traffic to them. Periodic decoding of paging channels can substantially increase battery life, since data transfer tends to be sporadic.

Once a mobile host has attached and activated a PDP context, it is able to exchange IP packets with the public Internet. A “ping” [Internet Control Message Protocol (ICMP) echo] message sent from a mobile host to a fixed host is carried over the radio access network to the SGSN currently serving the mobile. The source address of the IP packet carrying the ping message is the IP address assigned to the mobile during PDP context activation. The SGSN tunnels the ping message to the GGSN currently serving the mobile’s PDP context. The GGSN passes the ping message to the public Internet, where traditional IP routing is used to deliver the message to the fixed host. The fixed host echoes the ping message back to the mobile host. The destination IP address used by the fixed host is the IP address assigned to the mobile host during context activation. IP packets using the IP address of the mobile host are routed using traditional IP routing to the GGSN serving the mobile host’s PDP context. The GGSN tunnels the IP packet to the SGSN serving the mobile host. The SGSN then forwards the packet to the cell currently being used by the mobile host.

4.2.4.2. Mobile IP. Mobile IP is a protocol defined by the Internet Engineering Task force to deliver

Figure 6. Mobile IP mobility management architecture.

network layer packets to mobile hosts [7]. Here we highlight a few key differences between the mobile IP mobility management approach and the approach used in GPRS/EGPRS and UMTS networks.

Mobile IP high-level mobility management architecture is shown in Fig. 6:

- *Foreign Agent.* The foreign agent plays a role analogous to the SGSN in GPRS/EGPRS/UMTS networks. The foreign agent is responsible for sending and receiving network layer packets to the mobile host.
- *Home Agent.* The home agent plays a role analogous to the GGSN in GPRS/EGPRS/UMTS. Data packets sent to a mobile host are first routed to the home agent. The home agent then tunnels the packets to the foreign agent currently serving the mobile host. The foreign agent “detunnels” packets forwarded by the home agent and delivers them to the mobile host.

Mobile IP employs a technique known as “triangular routing” to transfer packets to and from mobile hosts. Network-layer packets sent from a corresponding host to a mobile host, are always routed via the home agent. However, packets sent by a mobile host to the corresponding hosts bypass the home agent, and are routed directly to the corresponding host. This is in contrast to the route traveled by packets sent by mobile hosts in GPRS/EGPRS/UMTS, where packets are always routed via the GGSN, regardless of the direction they are being sent—so-called bidirectional tunnels.

4.2.5. TCP over Wireless. TCP is the predominant wireline transport layer protocol used by internet applications [8]. TCP was designed to guarantee end-to-end reliable data delivery and end-to-end flow control over wireline networks. One key assumption underlies the design of TCP’s flow control and error recovery mechanisms—packet loss and delay are caused primarily by network congestion. In wireless data networks, however, packet loss and delay are caused primarily by airlink transmission errors. TCP flow control and error recovery mechanisms can cause severe end-to-end performance degradation when used over wireless links.

Two problems are encountered when TCP is used on wireless data networks. TCP has its own ARQ mechanism that often conflicts with the ARQ mechanism employed by a wireless data network’s RLC layer. TCP segments are typically divided into several RLC PDUs, which are then scheduled for transmission. When a wireless link is bad, many retransmissions occur in the RLC layer, increasing the delay experienced by individual TCP segments. If a TCP segment is not received within certain period of time, the TCP transmitter assumes that the segment is lost and retransmits it. However, the retransmission of the TCP segment is not necessary because the first TCP segment was not lost, but delayed as a result of airlink errors. These spurious TCP retransmissions waste airlink bandwidth and reduce TCP throughput.

Another problem with the use of TCP over wireless data networks is TCP’s end-to-end flow control mechanism. When TCP sees that a segment is delayed too much or lost, TCP “thinks” that there is congestion on the path between the transmitter and the receiver. Therefore, TCP reduces the transmission rate. When TCP receives a segment, it may think that the congestion has disappeared and then increases the transmission rate. However, the reason for packet delay fluctuation and loss is due mainly to the fluctuation of wireless link qualities and their induced network reactions. The way in which TCP reacts to packet delay and loss—quickly reducing transmission rates in response to excessive delay, and slowly increasing transmission rates when the delay decreases—is not well suited to the delays observed over wireless links. As a result, TCP transmission rate reductions may be too aggressive, and the wireless link may end up never fully utilized.

To solve the performance problems caused by using TCP over wireless data networks, the packet delay seen at the RLC layer should be made as smooth as possible. In this way, TCP will have an accurate estimate on the round-trip delay and then will not unnecessarily retransmit a packet or reduce the transmission rate. The delay jitter seen at the RLC layer may come from various sources, such as RLC retransmission and resequencing delay, connection teardown and resetup in the middle of a TCP session, and wireless scheduling. Although all of those causes may not be possible to eliminate, at least the designer should be aware of this and trade off the TCP problems against other considerations.

5. CONCLUSIONS

As a result of the interplay of each layer of the wireless data protocol stack, the need for spectrally efficient data transmission, the limitations placed by mobile terminal battery life, the design and engineering of wireless data networks offers many unique challenges. The wireless data networking technologies discussed in this article provide a variety of different approaches used to solve these problems.

BIOGRAPHIES

Wei Luo received a B.S. degree in electronic engineering from Tsinghua University, Beijing, China, in 1995 and

M.S. and Ph.D. degrees in electrical and computer engineering from University of Maryland, College Park, Maryland, in 1997 and 1999, respectively. Dr. Luo joined Bell Labs, Lucent Technologies in 1999 working on the performance, protocol and algorithm designs in wireless communication systems.

Kenneth C. Budka received his B.S. (summa cum laude) degree in electrical engineering from Union College in Schenectady, New York, in 1987 and M.S. and Ph.D. degrees in engineering science from Harvard University in Cambridge, Massachusetts, in 1988 and 1991, respectively. During his undergraduate and graduate studies, he was an exchange scholar at the Swiss Federal Institute of Technology (ETH) in Zurich, Switzerland, and Columbia University in New York, New York. Dr. Budka joined AT&T Bell Labs in 1991 working on control, resource allocation, scheduling, and performance issues arising in second and third generation wireless voice, and data communications technologies. He was named a Bell Labs Distinguished Member of Technical Staff in 1999, and currently works as a technical manager in Lucent Technologies Bell Labs High Performance Communication Systems Laboratory. A senior member of the Institute of Electrical and Electronics Engineers, Dr. Budka holds two patents in the area of wireless voice and data networks, with more than 10 others pending.

Krishna Balachandran received his B.E. (Hons) degree in electrical and electronics engineering from Birla Institute of Technology and Science, Pilani, India, M.S. in computer and systems engineering, M.S. in mathematics and Ph.D. in computer and systems engineering from Rensselaer Polytechnic Institute, Troy, New York. He joined Bell Labs, Lucent Technologies in 1996 as a member of technical staff and is currently an acting technical manager in the Networking Technologies and Performance Department at Bell Labs. His research interests include the design, analysis and simulation of advanced physical layer, media access control and radio link control protocols, link adaptation/hybrid ARQ techniques, resource allocation, and scheduling techniques for wireless systems. Dr. Balachandran has published over 30 journal and conference papers in related areas. He also holds three patents (several pending) and has contributed significantly to standardization activities in the TIA, ETSI, and 3GPP.

1. INTRODUCTION

Since the early 1990s, the sustained high pace of technological advances paved the way for the exponential growth of the Internet. We can trace the development of two implementation technologies as prime enablers of this growth. The first was the dramatic reduction in the cost of disks, namely, massive long-term storage. The second was the huge reduction in the cost of optical communication and its simultaneous capacity increase. More specifically, since 1991, the capacity of a \$100 disk increased by a factor of 1200, while during the same period, the bandwidth of optical cable doubled every 9 months. The Internet, as we know it today, is an exceptional educational, research, entertainment, and economic resource, which enables information to be available at the touch of a mouse. There is a wide consensus that the Internet will continue to grow rapidly in both quantitative and qualitative terms. At the same time, it appears that we are on the brink of the next technological revolution that may have even more profound impact on our lives. This revolution, that will enable any time, anywhere, communication and connection between the physical and computational worlds, is due to the advancement of wireless communication technology and sensors. While in the early 1990s wireless technology was mainly stagnant, since 1996, it has experienced an exponential growth. Wireless bandwidth in industrial offerings has increased by a factor of 28 from 1997 to 2002. On the other hand, recent progress in fabrication of micro-electromechanical systems-based (MEMS) sensors has opened new vistas in terms of cost, reliability, accuracy, and low energy requirements. While most of the MEMS-based sensors are still in the research phase, a boom in government funding in this area has resulted in amazing progress. For this field, the total funding was \$2 million in 1991 and \$35 million in 1995, while in 2001 it was estimated to have been \$300 million worldwide. With such advancement, there is currently a need for methodologies and technologies that will enable efficient and effective use of wireless embedded sensor network applications. The motivational factors pushing for these applications include the mobility of computational devices, such as cellular phones and personal digital assistants (PDAs), and the ability to embed these devices into the physical world.

Almost all of the modern science and engineering has been built using compound experiment–theory iteration steps. Typically, the experiments have been the expensive and slow components of the iterations. Thus, the existences of flexible yet economic experimentation platforms often result in great conceptual and theoretical breakthroughs. For example, advanced optical and infrared telescopes enabled spectacular progress in the understanding of large scale cosmology theory. Particle accelerators and colliders enabled great progress in the understanding the ultra small world of elementary particles. Furthermore, the progresses in computer science, information theory, and nonparametric statistics have been greatly facilitated by the ability to compile and execute programs quickly on general-purpose computers. Sensor networks will enable the same type of progress in better understanding many other sciences, not just by information processing, but also through new connections between the sciences and the physical, chemical, and biological worlds.

Sensor networks consist of a set of sensor nodes, each equipped with one or more sensors, communication subsystems, storage and processing resources, and in some cases actuators. The sensors in a node observe phenomena such as thermal, optic, acoustic, seismic, and acceleration events, while the processing and other components analyze the raw data and formulate answers to specific user requests. The recent advances in technology mentioned above, have paved the way for the design and implementation of new generations of sensor network nodes, packaged in very small and inexpensive form factors with sophisticated computation and wireless communication abilities. Once deployed, sensor nodes begin to observe the environment, communicate with their neighbors (i.e., nodes within communication range), collaboratively process raw sensory inputs, and perform a wide variety of tasks specified by the applications at hand. The key factor that makes wireless sensor networks so unique and promising in terms of both research and economic potentials is their ability to be deployed in very large scales without the complex preplanning, architectural engineering, and physical barriers that wired systems have faced in the past. The term “ad hoc” generally signifies such a deployment scenario where no structure, hierarchy, or network topology is defined a priori. In addition to being ad hoc, the wireless nature of the communication subsystems that rely on radio frequency (RF), infrared (IR), or other technologies, enable usage and deployment scenarios that were never before possible.

To illustrate the key concepts and a possible application of wireless ad hoc sensor networks (WASNs), consider the environmental monitoring requirements of large office buildings. Such buildings typically contain hundreds of environmental sensors (such as thermostats) that are wired to central air conditioning and ventilation systems. The significant wiring costs limit the complexity of current environmental controls and their reconfigurability. Furthermore, in highly dynamic corporate environments, cubicle offices may continuously be added, removed, and restructured, which makes environmental control rewiring an intractable task. However, replacing the hard-wired

monitoring units with inexpensive ad hoc wireless sensor nodes will easily improve the quality and energy efficiency of the environmental system while allowing unlimited reconfiguration and customization in the future. In addition to the classic temperature sensing, sensor nodes with multiple modalities (i.e., equipped with several different types of sensors) can significantly enhance the abilities of such a system. For example, motion or light sensors can detect the presence of people and even adjust the environmental controls using actuators, according to prespecified user preferences. In many instances, the savings in the initial wiring costs alone may justify the use of such wireless sensor nodes.

Although the environmental monitoring example above is an application of WASNs to a task that has existed for a long time, many new applications have also started to emerge as direct consequences of WASN developments. Such applications range from early forest fire detection and sophisticated earthquake monitoring in dense urban areas, to highly specialized medical diagnostic tasks where tiny sensors may even be ingested or administered into the human body. As mentioned above, personal spaces such as offices and living rooms can be customized to each individual by sensors that detect the presence of a nearby person and command the appropriate actuators to execute actions according to that person’s preferences. In essence, WASNs provide the final missing link connecting our physical world to the computational world and the Internet. Although many of these sensor technologies are not new, technological barriers and physical laws governing the energy requirements of performing wireless communications have limited their feasibility in the past. A few highlights and benefits of the newer, more capable sensor nodes are their abilities to

- Form very large-scale networks (thousands or more nodes).
- Implement sophisticated networking protocols as well as distributed and localized analysis algorithms.
- Reduce the amount of communication required to perform tasks by distributed and/or localized computations.
- Implement complex power-saving modes of operation depending on the environment, current tasks, and the state of the network.

In the following sections, we describe the generic components that form a wireless sensor network and highlight the key issues and characteristics that differentiate sensor networks from traditional peer-to-peer and ad hoc wireless communication networks. Section 2 lists the architectural and hardware related components, while in Section 3 the focus is on higher-level services and software issues. Section 4 provides a brief overview of the state of the art and the challenges ahead.

2. ARCHITECTURE AND HARDWARE

Similar to classical computer architectures, the main components of the physical architecture of WSN nodes

can be classified into four major groups: (1) processing, (2) storage, (3) communication, and (4) sensing and actuation [input/output (I/O)]. The following is a brief summary of the main issues involved and some related topics for each of these components.

2.1. Processing

Two key constraints for processing components are energy and cost. Essentially all current WSN processors are those used for mass markets. This is due in large part to the advantages of the economies of scale and the availability of comprehensive and mature software development environments for such processors. Since the processing in a node has to address a variety of different tasks, many nodes have several types of processors: microprocessors and/or microcontrollers, low-power digital signal processors (DSPs), communication processors, and application-specific integrated circuits (ASICs) for certain special tasks. The standard complementary metal oxide semiconductor (CMOS) process will be the technology of choice for sensor node processors at least until 2012.

2.2. Storage

Currently, sensor nodes have relatively small storage components. They most often consist of standard dynamic random access memory (DRAM) and relatively large quantities of nonvolatile (flash) memory. Since the communication is a dominant component of the overall energy consumption in wireless sensor networks, we expect that the amount of local storage at a node will continue to increase. This expectation is further enforced by the fact that since 1992, the cost of memory was declining much faster than the cost of processors. We also expect that new technologies, in particular magnetoresistive random-access memory (MRAM), will soon be widely used for this type of storage.

2.3. Communication

The communication paradigms often associated with the current generations of wireless sensor networks are multihop communication. Several current results indicate that multihop communications scale very well and can significantly reduce the energy consumption in large sensor networks [1]. A number of new projects are currently targeting low power communication. This is an area where it is most difficult to predict how technology will impact future architectures, since commercial wireless communication is a relatively new field. It is very important to note here that in typical low-power radios used in WSN communication, listening often requires as much energy as transmitting. This is in sharp contrast to the assumptions made in most previous work in ad hoc multihop networking, where sending a message was believed to have been the major consumer of energy. These new constraints indicate that the study of complex power saving modes of operation, such as having multiple different sleep states, will be crucial in this field.

2.4. Sensors and Actuators

One can envision the sensors as the eyes of the sensor network, and the actuators, as its muscles. Although MEMS technology has been making steady progress since the early 1960s, it is obvious that it is still in its early phases where development is mainly sustained by research funding and not yet commercial. However, significant results have already been obtained. A good starting point for learning more about sensor systems is the article by Mason et al. [2].

3. SYSTEM SOFTWARE AND APPLICATIONS

As described above, the recent advent of WASNs has required completely new approaches for building system software and optimization algorithms, as well as the adaptation of existing techniques. It is interesting and important to analyze why the already existing distributed algorithm techniques were not directly applicable to WASNs. There are at least five major reasons: (1) WASNs are intrinsically related to the physical and geometric world and therefore have very special properties—the uses of local and geographic information, for example, play key roles in designing efficient, robust, and scalable sensor networks; (2) relative communication costs are much higher than they were assumed to be in all previous distributed computing research—since WASN nodes are severely energy constrained, the cost of communication becomes an extremely important factor in the design of WASN software; (3) accuracy of physical measurements is intrinsically limited and therefore there is little advantage on insisting on completely accurate results; (4) energy consumption is a critical system constraint; and (5) data acquisition is naturally distributed and error-prone, implying a strong need for new sensing, computation, and communication models.

The relative communication delay in sensor networks is significantly larger than in traditional computational systems. It is interesting to note that in modern deep submicrometer (DSM) chip designs, delay on a single system-on-chip will be up to 20 clock cycles. However, even the fastest communication protocols in WASNs will have delays in millions of cycles due to technological and physical limitations as well as system software overhead. Furthermore, communication generally dominates both sensing and computation in terms of energy (currently, image and video sensors are exceptions). Again, it is interesting to draw parallels with DSM designs: In DSM, communication will also dominate power consumption, maybe eventually by as high as a 10:1 ratio with respect to computations. In WASNs, technology trends are much more difficult to predict, yet at least in current and pending technologies, this ratio is much higher, often estimated at 1000:1.

Interestingly, several new hardware and architectural characteristics have also come into play that strongly influence WSN communication costs. For example, we have already mentioned that in many of the current low-power radios used in WSN nodes, the power requirements for listening or receiving messages is

about the same as when transmitting. This is in sharp contrast to the assumptions made in numerous wireless communication research efforts in the past, where transmitting a message was almost always assumed to have required much more power than listening or receiving a message. Consequently, in order to be truly effective, WASN system software must try to maximize the duration of the times when the communication subsystems can be turned off or placed in sleep modes, thus saving precious reserve energy resources.

In addition to placing nodes in sleep modes to conserve energy, one can expect that fault tolerance and autonomous operation will be essentially mandatory for large scale WASNs, due to wide-scale deployment and the relatively high cost of servicing nodes. During the useful lifetime of a typical WASN, it is not unreasonable to expect that at least some nodes will exhaust their energy supply. Even if latency (real-time constraints), energy consumption, and fault tolerance were not an issue, security and privacy issues would very often mandate that only a subset of nodes participate in a specific task. In addition, sensor nodes are often deployed outside strictly controlled environments, communicate using wireless (insecure) media, and hence are highly susceptible to security attacks. This further indicates that expecting all nodes to always be able to sense, communicate, and compute is not realistic. Moreover, as WASNs evolve into an Internet-like scale and organization and span the whole earth and beyond, the only realistic possibility for all tasks will be execution in highly localized scenarios. In localized computation models, only a subset of nodes, which are almost always within geographic proximity, collaborate and participate in formulating results to specific application tasks.

The challenges outlined above can be classified into three major categories: (1) strict constraints; (2) new modes of operation; and (3) interface between physical world, computation, and information theory. The "strict constraint" challenges include problems related to the need for low cost, long life, and reliable infrastructures. Low-power operation, wireless bandwidth efficiency, reliability, fault tolerance, high availability, error recovery, distributed synchronization, and real-time operation in unpredictable environments are all important factors that influence the design decisions at this step. In this direction, the current key problem is learning how to scale the already available techniques to the next levels of strictness of constraints.

There are two main research direction related to the "new modes of operation" of WSNs, due to their distributed and multihop natures: localized algorithms and autonomous continuous operation. *Localized algorithms* are algorithms implemented on sensor networks in such a way that only a limited number of nodes communicate, therefore reducing overall energy consumption and bandwidth requirements. Consequently, localized algorithms often operate with incomplete information, noisy data, and almost always under very strict communication and energy constraints.

One way of modeling localized algorithms in WASNs is as follows: One or more nodes initiate a request for a computation (a query). The result of the query is to be sent to one or more sink nodes. Each node can obtain its required information either through its sensors or by communication with neighboring nodes. The goal is to maximize an objective function for the optimization task at hand, in such a way that all constraints are satisfied and the communication cost is minimal. The first and most important difference between the localized algorithm and other traditional methods is the amount of information available to the processing units. In conventional scenarios, the processors have all the information that is needed for their computation tasks. However, in localized approaches, the required information is not complete and thus the communication between components should be interleaved with the computations in different parts so that they compensate for the insufficient information. The other interesting aspect of localized procedures is that although there are many processing units in a pervasive computing environment such as WASNs, for most of the applications, only a few processors are sufficient to carry out the required calculations. This is in contrast to the classical distributed computing paradigms where all processors involved in a computation are actively computing all the time. For centralized algorithms, of course, one processing unit handles all the computations and control. In addition to the localized nature of the optimization algorithms in WASNs, autonomous closed-loop modes of operation are a must for effective use of such networks. Essentially, the applications must execute with minimal or no intervention of a human operator.

Traditional wired and wireless computer communication network designers have typically followed (although often loosely) the International Organization for Standardization (ISO¹) Open System Interconnection (OSI) Reference Model as the basis for their protocol stack design. The OSI Reference Model specifies seven protocol layers: physical, data link, network, transport, session, presentation, and application [3]. The following subsections briefly describe two main WASN protocol stack layer functions, namely, medium access control (MAC) and routing, which are equivalent to what the OSI model classifies as data-link- and network-layer functions, respectively. The subsequent sections then describe sensor network specific tasks and problems such as location discovery and coverage.

3.1. Medium Access Control (MAC)

Wireless communication media are almost always broadcast in nature and thus are shared among the participants. For example, RF transmissions of one node can be "heard" by any other node that is within communication range. If two nodes that are close together transmit at the same time, their transmissions will most likely "collide" and interfere with each other. *Medium access*

¹ ISO is not an acronym. ISO is an international standardization organization with members from more than 75 countries.

control refers to the process by which nodes determine when and how to utilize a shared communication medium. In WASNs where network communications are multihop (often require intermediate nodes to forward packets), the MAC layer is also where specific self-organization and autonomous configuration abilities can be introduced into the network.

Traditional MAC designs have followed two distinct philosophies: dedicated and contention-based. In the *dedicated* scenarios, each node receives the shared resource according to a prespecified scheme. Time-division multiple access (TDMA) is one such scheme where each node may only transmit within a small, periodic, time slot. Such MAC strategies are typically not well suited for ad hoc networks that have no predefined organization and can be very dynamic in nature; that is, nodes can join, move, or leave the network at any time. In *contention-based* schemes, nodes attempt to “grab” the medium and transmit when needed. Often, nodes have abilities to sense that a channel is in use and thus determine that they must wait. References 4 and 5 provide an overview of existing techniques and propose new MAC layer schemes that are designed specifically for WASNs.

3.2. Ad Hoc Routing

Routing refers to the process of finding ways to deliver a message from a source to its destination. In ad hoc, multihop networking scenarios, routing is an especially difficult problem since the nodes must discover the destination and the routes to the destinations subject to extreme energy consumption limitations. Existing works from ad hoc wireless networking domains provide a solid foundation for WASN routing problems. However, WASNs have unique features that make traditional routing philosophies less relevant. In traditional wired and wireless data communication networks, connections are peer-to-peer. This means that the user at a specific source node must send data (usually in forms of packets) to another user at a specific destination. Consequently, the endpoints of communication typically have unique names and specific communications are identified by the source and destination names (addresses). In WASNs, however, such peer-to-peer communications are less meaningful. Typically, nodes that sense events, analyze the data, collaborate with neighbors, and communicate processed information to one or more sink nodes. In addition, the information may be processed further along the path to the destination which makes the definition of “routing” very vague in WASNs compared to traditional data communication networks.

“Flooding” is a well-known basic scheme that can be used for routing in any network. During flooding, each intermediate node that receives a packet simply forwards it to all its neighbors until it reaches the destination. In a connected network, the packet will most likely reach the destination, although packet losses due to interference and other transmission errors are always possible. Although for broadcast messages flooding is very effective, the overhead for point-to-point communication is extremely high. Other more sophisticated approaches

have been proposed such as dynamic source routing (DSR) and ad hoc on-demand distance vector (AODV) routing, which try to discover routes and maintain information about the network topology to eliminate flooding overheads. Reference 6 provides an overview and detailed analysis of several ad hoc network routing protocols. However, as stated above, routing schemes from ad hoc networking do not necessarily work well in sensor networks.

Several schemes have been proposed for routing in WASNs that leverage on sensor network specific characteristics such as geographic information and application requirements. Because of the immaturity of the field, none have established themselves as definitive solutions to WASN routing. Directed diffusion is one example of a generic scheme for managing the data communication requirements (and thus routing) in WASNs. The basic scheme in directed diffusion proposes the naming of data as opposed to naming sources and destinations of data. Data are “named” using attribute–value pairs. Data are requested by name as “interests” in the network. The request (dissemination) sets up “gradients” so that the named data (or events) can be “drawn.” In traditional IP-style communication, nodes are identified as “endpoints” and the communication is layered as an end-to-end service. In directed diffusion, in contrast, named data flow toward the originators of their corresponding interests along multiple paths with the network “reinforcing” one or multiple such paths [7]. However, as stated above, WASN nodes may process the data at intermediate steps and the specific routing solution may be tightly coupled with application tasks (as opposed to layered).

3.3. Location Discovery

Geographic information is an integral attribute of any physical measurement. Thus, the knowledge of node locations is fundamental in proper operations of sensor networks, especially for WASNs. The ad hoc nature of WASN deployment necessitates that each node determine its location through a location discovery process. The Global Positioning System (GPS) is one method that was designed and is controlled by the United States Department of Defense for this purpose. The GPS system consists of at least 24 satellites in orbit around the earth, with at least four satellites viewable from any point, at a given time, on earth. They each broadcast time-stamped messages at periodic intervals. Any device that can hear the messages from four or more satellites can estimate its distance from each satellite and thus perform trilateration to compute its position.

Although GPS is an elegant solution to the location discovery process, it has several limitations that hinder its use in WASN applications: (1) GPS is costly in terms of both hardware and power requirements and (2) it requires line-of-sight communication between the receiver and the satellites and thus does not work well when obstructions such as buildings, trees, and mountains block the direct “view” to the satellites. Thus, other techniques have been proposed to dynamically compute the locations of the nodes in WASNs. In several location

discovery schemes, the received signal strength indicator (RSSI) of RF communication is used as a measure of distance between nodes. In other schemes, the time difference in arrival of RF and acoustic (ultrasound) signals are used to approximate node distances. Once nodes in a WASN have the ability to estimate distances between each other (ranging), they can then compute their locations using the simple trilateration method. In order for a trilateration to be successful, a node must have at least three neighbors who already know their locations. This requires that at least a subset of nodes determine their locations through other means such as by using GPS, manual programming, or deterministic deployment (placing nodes at specified coordinates). References 8 and 9 provide detailed discussions on location discovery techniques and algorithms.

3.4. Coverage

Several different coverage formulations arise naturally in many domains. The “art gallery problem,” for example, deals with determining the number of observers necessary to cover an art gallery room such that every point is seen by at least one observer. This problem has several applications such as for optimal antenna placement problems in wireless communication. The art gallery problem was solved optimally in two dimensions (2D) [10] and was shown to be computationally intractable in the 3D case. Coverage in the context of sensor networks can have very new semantics. The main question at the core of coverage is trying to answer how well the sensors observe a physical space. References 11 and 12 present several formulations of sensor coverage in sensor networks. The formulations include calculations based on best- and worst-case coverages for agents moving in a sensor field and exposure-based methods. In the best- and worst-case formulations, the distance of the agent to the closest sensors are of importance, while in exposure-based methods the detection probability (observability) in the sensor field is represented by a path-dependent integral of multiple sensor intensities. In both of these schemes, the types of actions that the agent performs impact the coverage metric. For example, the sensor field may have a different coverage level if an agent is traveling west to east as opposed to north to south, or along any other arbitrary paths. The actual physical characteristics and abilities of WASN nodes will play crucial roles in building practical, accurate, and useful coverage models and analysis algorithms.

4. FUTURE DIRECTIONS

We conclude by summarizing some important future challenges in wireless sensor networks:

QoS. For quality of service (QoS), one can define both syntactic and semantic interpretations. On the syntactic level, one can consider dimensions such as coverage, exposure, latency, measurement and communication errors, and event detection confidence. On the semantic level, one can define

utility and cost functions to enable the analysis of how particular data can help in the construction of more accurate models of the physical world or more efficient algorithms.

Scaling. Scaling has been the key metric in analyzing both graph-theoretic and physical phenomena. The goal will be to develop new methods that are based on statistical techniques instead of traditional probabilistic ones. Existing techniques such as state transitions and percolation will be key factors in analyzing and building very large systems and optimizing their performance.

Profilers, Recommenders, and Search Engines. Profilers, recommenders, and search engines rapidly emerged as mandatory systems enabling efficient use of the World Wide Web (WWW) and the Internet. There are clear needs to develop such systems for sensor networks. New dimensions and challenges include ways to include information and knowledge, not just about physical location and physical time, but also about the physical, chemical, and biological worlds. There are needs for profilers of events, objects, areas, sensors, and users, among other things.

Foundations and Theory. There is a need to develop new theoretical foundations, new models, new algorithmic complexity theory and practice, new programming models, and languages for embedded sensor networks. For example, new models of sensor networks will encompass the already existing Markov models, interacting particle models (e.g., the Ising model), bifurcation-based models, fractals, oscillations, and space pattern models. In addition, there will be a need to create new models unique to wireless sensor networks. As another example, the VLSI (very large scale integration) theory field was built based on two lasting premises: (1) that integrated circuits are planar and (2) that features are of small size, yet limited in quantity. There is a need to explore such lasting features in sensor networks. Examples of such rule-based modeling are “energy spent on communication is dominant and distance-dependent,” “all measurements have intrinsic errors,” and “storage space on nodes is very limited.”

Other potential research directions include validation and debugging, data compression and aggregation, real-time constraints, distributed scheduling and assignment, pricing, and privacy of actions.

BIOGRAPHIES

Seapahn Megerian (Meguerdichian) is currently a Ph.D. student in the Computer Science Department at the University of California, Los Angeles. He received his Computer Science and Engineering B.S. degree in 1998 and Computer Science M.S. degree in 1999 from UCLA. His primary focus is in the design and development of efficient algorithms for deployment,

performance, and coverage analysis; decision support; operation optimization; security; and privacy in wireless ad hoc sensor networks. In addition, his research includes high-performance communication systems, system-on-chip network design, application-specific compilers, and computational security. He was the recipient of the 7th Annual International Conference on Mobile Computing and Networking (MobiCom 2001) Best Student Paper Award for the paper titled "Exposure in Wireless Ad Hoc Sensor Networks."

Miodrag Potkonjak is a Professor in the Computer Science Department at the University of California, Los Angeles. He received his Ph.D. degree in Electrical Engineering and Computer Science from University of California, Berkeley in 1991. In 1991, he joined C&C Research Laboratories, NEC USA in Princeton, New Jersey. Since 1995, he has been with UCLA. He has received the NSF CAREER award, OKAWA foundation award, UCLA TRW SEAS Excellence in Teaching Award, and a number of best-paper awards. His research interests include complex distributed systems, communication system design, embedded systems, computational security, practical optimization techniques, and intellectual property protection.

 slotted, 142
 smart antennas in, 163
 space and time optimization in, 163–164, **163**, **164**
 spatial division multiple access in, 163
 spatial processing, 163
 spherical conformal, 152–153
 spherical coordinates of, 142
 supergain in, 160–161
 synthesis as optimization problem in, 160, 187
 Taylor distribution (Chebyshev error) and, 154–157, **155**, **157**, 187
 Taylor one-parameter distribution in, 155
 thinned arrays in, 162–163
 3D, 151–152, **152**
 time division multiple access in, 163
 total electric field in, 142
 total magnetic field in, 142
 uniform linear, 144–145, **146**, 153, **153**
 visible region in, 144
 Woodward–Lawson method and orthosynthesis in, 158–159, **159**, 187
 Yagi–Uda, 161, **161**, 187
 antenna beam switching, satellite onboard processing and, 478–479
 antenna duplexers, surface acoustic wave filters and, 2458–59
 antenna index, 160
 antenna modeling techniques, 169–180, 182–184
 absorbing boundary conditions in, 177
 adaptive integral method (AIM) in, 173
 Ampere–Maxwell laws in, 171
 aperture source modeling in, 183–184, **183**
 assembly process in, 177
 basis functions in, 174, 175
 boundary element/boundary integral methods in, 176
 coupling integrals in, 174
 differential approach to, 170
 Duffy's transform in, 174
 electric field integral equation in, 173
 entire-domain basis functions in, 174
 expansion coefficients in, 174
 expansion coefficients in, 176–177
 Faraday law and, 171
 fast algorithms in, 173
 fast Fourier transform in, 173
 fast multipole method in, 173
 field equivalence principle in, 183–184
 finite element (FE) method for, 170, 176–177, **176**
 finite-element boundary integral methods in, 170, 177
 frequency domain based, 169, 170

antenna modeling techniques (*continued*)

gain in, **170**
 Galerkin method in, 174, 177
 Gauss elimination in, 173
 Green function in, 172, 174, 176
 Helmholtz equations in, 171
 Huygen's principle in, 183–184
 hybrid techniques for, 170, 177
 integral approach to, 170, 172–176
 Kirchhoff's current law and, 175
 lower-upper decomposition in, 173
 magnetic field in, 171
 Maxwell's equations and, 169, 170–172, 176
 method of moments in, 173, 174, 175
 Nystrom's method in, 173
 perfect electric conductor in, 183–184
 permeability in, 171
 permittivity in, 171
 point matching or colocation method in, 174
 quadrilateral grid in, for onboard auto antennas, **171**
 Rao–Wilton–Glisson basis functions in, 176
 rooftop basis functions in, 176
 slot antennas and, **170**
 source current and spherical boundary in, 171, **171**
 source modeling and, 182–184
 Strat–Chu equation in, 172
 subdomain basis functions in, 174, 175–176
 surface equivalence principle in, 172, **172**
 surface modeling in, 175–176, **176**
 thin-wire theory in, 175
 time domain based, 169
 time domain/integral equation methods in, 169
 weighting functions in, 175
 weighting in, 176
 wire modeling in, 174–175, **174**, **175**, 182–183, **183**
 antennas, 179–188

absorbing boundary conditions in, 177
 active (see also active antennas), 47–68
 adaptive, 180, 184, 192, **192**
 adaptive arrays (see adaptive antenna arrays)
 aeronautical communications, 198–199
 Ampere–Maxwell laws in, 171
 aperture efficiency in, 186
 aperture source modeling in, 183–184, **183**
 aperture-type, 180, 184
 arrays of (see antenna arrays)
 atmospheric refraction and, 210–211, **210**
 bandwidth in, 144, 169, 180
 beamforming, 191–192, **192**, 480
 beamwidth and, 185
 beverage, 1259
 Bluetooth, 169
 broadpattern pattern, 180
 built in, 194–195
 categories of, 188
 cavity backed cross slot, 197–198
 cellular communications channels and, 393
 cellular telephone, 169, 183, 189, **189**
 chip, 195–196
 cochannel interference and, 454–455
 conformal, 169
 cordless telephone, 189
 corner reflector, 191, **191**
 coupling in, 160
 crossed dipole, 199
 crossed drooping dipole, 197, **197**
 crossed slot, 199
 dead zones and, 215
 diffraction in, 213–215, **214**, **215**, 215–216
 dipole (see dipoles)
 directional, 198
 directivity gain in, 142
 directivity in, 180, 185, **186**, 196
 divergence factors in, 211
 dual beam, 191, 194
 dual frequency, 191, 194
 early researches into, 179
 earth reflection and, 209–210, **209**
 effective area of, 180, 186
 electric field in, 180
 electrical equivalents in, 180
 elements of, 180
 elements, in arrays, 144
 fan, 180
 far field (Fraunhofer) region in, 181–182, **182**
 Faraday law and, 171
 feeds for, 166, **166**, **167**
 field equivalence principle in, 183–184
 field regions in, 181–182, **182**
 figures of merit for, 180, 184–186
 four-third's earth radius concept in, 210
 free space propagation equations in, 208–209, **209**
 frequencies and, 179, 180, 190, 191, 192, 193
 frequency independent, 180
 Fresnel reflection coefficient for, 209
 Fresnel zones and, 214
 Friis equation in, 2015
 gain in, 169, 185–186, 190, 192–193, 196
 gain to system noise in, 196
 Global System for Mobile and, 194
 Green function in, 172, 174, 176
 ground reflection point, 209–210
 half power beamwidth of, 143, 153, 185
 half wave, 193
 helical and spiral, 180, 183, 193–194, **193**, 935–946, **936–945**
 Helmholtz equations in, 171
 high frequency (HF) communications and, 951
 high gain, 169
 horn, 179, 180, 184, 187, 1006–17, **1006**, 1392, **1392**
 Huygen's principle in, 183–184, 214
 impedance and, 160, 169, 177, **177**, 180, 184, 186
 index of, 160
 indoor propagation models and, 2015
 isotropic radiator, 185
 Kirchhoff's current law and, 175
 klystron, 179
 leaky wave, 1235–47
 lens type, 180
 linear, 1257–60
 lobes in, 184
 log periodic, 169, 187
 long wire, 180, 188
 loop, 183, 1290–99
 loss in, 186
 magnetic field in, 171, 180
 magnetron, 179
 main (major) lobe in, 184
 Maxwell's equations and, 169, 170–172, 176, 179, 180–181
 meander, 193, 194, **194**
 method of moments in, 173, 174, 175
 microstrip, 180, 184, 193
 microstrip/microstrip patch (see microstrip/microstrip patch antennas)
 microwave, 179, 180, 2567
 military, 169
 millimeter wave, 1423–33
 mobile communication (see also antennas for mobile communications), 169, 188
 modeling (see antenna modeling techniques)
 monopole, 183, 193, **193**
 multibeam phased arrays and, 1513–21, **14**
 multiple antenna transceivers for wireless communications, 1579–90, **1580**
 multiple input/multiple output systems and, 1450–56, **1450**
 near grazing incidence in, 210
 null beamwidth in, 143
 Nystrom's method in, 173
 omnidirectional, 197–198
 paging system, 183
 parabolic, 1920–28, **1920**
 parameters of, 184–186
 patch, 169, 180, 193
 path loss and, 216–217, 1936–44
 pattern beamwidth and, 169
 perfect electric conductor in, 183–184
 planar inverted F, 193, 195, **195**
 plane radiation pattern, principle plane in, 142–144, **143**
 polarization diversity, 191

polarization efficiency in, 186
 polarization in, 142, 180, 186, 196
 power density in, 185, 186
 power gain in, 143
 propagation factor or path gain factor in, 209
 proximity effects and, 189
 quad helical, 198
 quadrifilar helical, 197, **197**, 199
 quality factor in, 143, 199
 quarter wave, 193
 radiating near field (Fresnel) region in, 181–182, **182**
 radiation density in, 185
 radiation efficiency in, 143, 184–186
 radiation intensity in, 142–143, 185
 radiation patterns and, 142–144, **143**, 160, **175**, 180–181, **181**, 184, 190, 192, 193
 radiator, 180, 199
 Rayleigh criterion and, 212–213, **213**
 reactive near field region in, 181–182, **182**
 reflector, 169, 179, 180, 184, 187, 2080–88
 resistance in (radiation and loss), 184
 rhomboid, 180
 roughness factors (specular effects) and, 211–213, **212**, **213**
 rubber duck and, 193
 satellite, 169, 189, 196–199, 477–479, 877–878
 scattering and, 215
 short backfire, 198, **198**
 sidelobe level in, 144, 184
 sidelobes in, 169
 signal to noise ratio in, 143
 slot, 169, 180
 smart, 180, 184, 187, 191
 Snell's law and, 210
 space-time coding and, 2324–32, **2324**
 spatiotemporal signal processing and, 2333–40, **2333**
 standing wave, 1257
 Strat–Chu equation in, 172
 supergain in, 160–161
 surface equivalence principle in, 172, **172**
 surface roughness (specular effects) and, 211–213, **212**, **213**
 switched beam, 191–192
 television and FM broadcasting, 180, 187, 2517–36
 theory of, 180–182
 Thevenin equivalent circuits and, 184, **185**
 thin-wire theory in, 175
 transverse electromagnetic waves and, 182
 waveguide aperture, 179
 waveguides and (see waveguides)
 wire modeling in, 174–175, **174**, **175**
 wireless communications and, 169, 179–180, 183, 184, 190
 Yagi–Uda, 169, 187
 antennas for mobile communications, 188–200
 adaptive, 192, **192**
 aeronautical communications, 198–199
 bandwidth in, 190
 base station, 190–192
 beam tilting in, 190, **190**
 beamforming, 191–192, **192**
 built in, 194–195
 carrier to noise level ratio in, 190
 cavity backed cross slot, 197–198
 cellular telephone, 189, **189**
 chip type built in, 193
 chip, 195–196
 cordless telephone, 189
 corner reflector, 191, **191**
 crossed dipole, 199
 crossed drooping dipole, 197, **197**
 crossed slot, 199
 design of, 189–193
 directional, 198
 directivity in, for satellite communications, 196
 diversity reception in, 190
 dual beam, 191, 194
 dual frequency, 191, 194
 fading in, 190
 frequencies for, 190, 191, 192, 193
 frequency domain duplexing, 190

antennas for mobile communications (*continued*)

 couplers and coupling
 active antennas and, 52
 adaptive antenna arrays and, 68–69, 70, 73–77, **74**, **75**, **76**, **77**, 74
 antenna arrays and, 160, 164–166, **165**, **166**
 antenna modeling and, integrals in, 174
 high frequency communications and, 951
 microstrip/microstrip patch antennas and, 1370–1371, **1371**, **1372**, **1373**
 optical fiber and, 1697–1700, **1697–1700**, 1707, 1715, **1715**
 powerline communications and, 1998–99
 coupling coefficient, optical couplers and, 1698
 coupling loss, diffraction gratings and, 1751–52, **1753**
 covariance, adaptive antenna arrays and, 68
 coverage area or footprint
 cell planning in wireless networks and, 372
 satellite communications and, 1249, 2111
 wireless LANs and, 2678
 wireless packet data and, 2985
 wireless sensor networks and, 2995
 Cramer–Rao bound, 402, 403, 405, **405**, 1339
 Cramer–Rao lower bound, 2055
 credit-based control schemes, ATM and, 551
 credit weighted algorithms, medium access control and, 1556
 creeper algorithm, sequential decoding of convolutional coding and, 2154
 critical frequency, 2065, 2066
 cross correlation
 diversity and, 729
 feedback shift registers and, 796
 Gold sequences and, 901–902
 polyphase sequences and, 1975
 pulse position modulation and, 2042
 signature sequence for CDMA and, 2276–85
 ternary sequences and, 2542–43
 cross coupled IQ transmitter, minimum shift keying and, 1467, **1467**
 cross gain modulation
 signal quality monitoring and, 2273
 wavelength division multiplexing and, 756
 cross modulation, community antenna TV and, 516–517
 cross phase modulation
 optical communications systems and, 1490–91, **1490**, 1684, 1686–87, **1687**, 1712, 1844, 1846
 solitons and, intrachannel, 1769–70
 wavelength division multiplexing and, 756
 cross polarization, local multipoint distribution services and, 1277, **1277**

- cross validated minimum output variance rule, 1895, 1898
- crossbar switch, ATM and, 202–203, **202**
- crossed dipole antenna, 199
- crossed drooping dipole antenna, 197, **197**
- crossed slot antenna, 199
- crossover probability, automatic repeat request and, 230, **230**
- cross-spectral reduced-rank method, adaptive receivers for spread-spectrum system and, 104
- crosstalk
 - cellular communications channels and, 397
 - diffraction gratings and, 1752
 - digital magnetic recording channel and, M7, 1325
 - optical couplers and, 1699
 - optical cross connects/switches and, 1784–85
 - optical fiber systems and, 1843
 - optical signal regeneration and, 1759
 - photonic analog to digital conversion and, 1965
 - very high speed DSL and, 2786, 2798–2800, 2803–05, **2805**

- path loss and, 1940
- radiowave propagation and, 213–215, **214**, **215**, 215–216
- unified theory of diffraction and, 216, 1936, 1942, 2018
- diffraction gratings (see also Bragg gratings; optical multiplexing/demultiplexing), 1723–26, **1723**, **1726**, 1749–56

- diffraction gratings (see also Bragg gratings; optical multiplexing/demultiplexing) (*continued*)
 acoustooptical gratings in, 1755–56, **1756**
 arrayed waveguide grating in, 1752–54, **1753**
 Bragg condition in, 1756
 classification of, 1750–51
 concave, 1755
 coupling loss and, 1751–52, **1753**
 crosstalk and, 1752
 Czerny–Turner spectrograph configuration in, 1751, **1752**, 1754
 demultiplexer performance and, 1751–52
 diffraction in, 1750
 Ebert–Fastie spectrograph configuration in, 1751, **1752**, 1754–55
 far field intensity in, 1749–50
 focal curves in, 1751
 free space gratings in, 1754–55
 holographic concave gratings in, 1755, **1755**
 lasers and, 1779
 operation of, 1749–50, **1751**
 optical multiplexing and demultiplexing and, 1749–56, 1758
 Rayleigh criterion in, 1750
 retroreflectors in, 1755
 Rowland circle in, 1751, **1752**
 spectrograph overview of, 1751, **1752**
 STIMAX free space grating, 1754–55
 two dimensional concave gratings in, 1754
 Vernier effect and, 1780
- diffusion, in photodetectors, 999–1000
 diffusion concept, in cryptography, 606
 digital advanced mobile phone system, 397
 digital audio broadcasting, 321, 677–686
 advantages of, 678
 amplitude modulation and, 679–80
 audio coding in, 681–682
 channel coding in, 683–684, **683**
 digital signal processing and, 677–678
 distortion and, 677
 Eureka 147 DAB system in, 680–685
 frequency bands for, 679–80
 frequency modulation and, 679–680
 global positioning system and, 685
 history and development of, 678–680
 integrated services broadcasting system in, 680
 interference and, 677
 masking in, 682, **682**
 modulation in, 684
 MPEG compression and, 682–683
 multipath and, 677, **678**
 multipath and, 685–685, **685**
 narrow band digital broadcasting in, 680
 network for, 684–685
 orthogonal frequency division multiplexing and, 678–679, 684
 satellite digital audio radio service and, 680
 single frequency networks in, 679, **679**
 transmitters for, 681, **681**
- digital audio tape, 1319
 digital audio/video broadcasting, 2481, 2941
 digital audio-visual council, 318, 320
 digital beamforming antenna arrays, 142, 163–164
 digital cross connect, 1634
 digital elevation models, 374, 2561
 digital enhanced cordless telecommunications, 1096–1108, 1289, 1350, 2952, 2955
 Digital Equipment Corporation, local area networks, 1279
 digital filters, 686–702
 digital magnetic recording channel, 1322–1326, **1326**, **1327**
 channel identification in, 1326
 channel in, 1323–1324
 distortion in, 1325–1326
 dropouts in, 1326
 finite impulse response equalizers and, 1324
 head noise in, 1325
 intersymbol interference and, 1325, 1326
 intertrack interference (crosstalk) in, 1325
 Lorentzian transition response in, 1324–1325, **1324**, 1328–1329, **1329**
 media noise in, 1325
 M-H curve in, 1322–1326, **1326**
 normalized linear density in, 1324
 partial erasure in, 1326
 preamplifier noise in, 1325
 pulse amplitude modulation in, 1323
 read process in, 1323–1324
 thermal asperity in, 1326
 transition shift in, 1325, **1325**
 write process in, 1323–1324
- digital modular radio, 2306
 digital phase modulation, 709–719
 additive white Gaussian noise, 709
 amplitude shift keying in, 709–719
 bandwidth, 709, 710
 binary phase shift keying, 710–711
 bit error rate in, 709
 continuous phase modulation in, 710
 frequency shift keying in, 709–719
 Nyquist criterion, 709
 phase shift keying in, 709–719
 power efficiency in, 709
 quadrature phase shift keying and, 710, 711
- digital signal processing
 in acoustic modems for underwater communications, 17, **17**
 acoustic telemetry in, 23
 blind equalizers and, 296
 digital audio broadcasting and, 677–678
 digital filters and, 686–687
 discrete multitone and, 740–741
 in underwater acoustic communications, 36
 shallow water acoustic networks and, 2207
 simulation and, 2285
 software radio and, 2304, 2306, 2316
 synchronization and, 2472–85
 underw/in underwater acoustic communications, 43–44
 wireless MPEG 4 videocommunications and, 2973
- digital signature algorithm, 612–613
 digital signature standard, 1649
 digital signatures (see also authentication), 218, 606, 607, 612–613, 1649
 digital simultaneous voice and data, 2340
 digital subscriber line, 272, 2653, 2654, 2779–2807, **2781**, 2915
 access multiplexer for, 272
 asymmetric, 1570, 1571–72, **1571**
 blind equalizers and, 287, 296
 broadband and, 2655, 2666–73, **2670**
 broadband wireless access and, 317
 compression and, 1570–71
 integrated services digital networks and, 1570
 layered coding in, 1570–71
 modems and, 1499–1500
 MPEG compression and, 1571
 multimedia over, 1570–79
 powerline communications and, 1995
 quality of service and, 1571
 satellite communications and, 2121
 unequal error protection coding and, 2767
- digital subscriber line access multiplexer, 272, 2784
 digital terrain elevation data, microwave, 2561
 digital terrain models, cell planning in wireless networks, 372
- digital to analog converter
 in acoustic modems for underwater communications, 17
 cable modems and, 333–334
 digital filters and, 686–687
 frequency synthesizers and, 833–835, **834**
 modems and, 1495
 orthogonal frequency division multiplexing and, 1871
 sigma delta converters and, 2227–47, **2228**
 software radio and, 2305, 2306, 2308, 2313
 speech coding/synthesis and, 2370
 wireless multiuser communications systems and, 1609
- digital transmission, telephone, 262
 digital TV, very high speed DSL, 2780
 digital versatile disk (see also optical memories), 1319, 1733–41, **1734**, **1737**
 capacity of, 1737
 content protection for recordable media, 1738
 data search information in, 1738
 DVD-ROM media in, 1738
 high definition TV and, 1738
 MPEG compression and, 1738
 multilayered memory in, 1737
 NTSC standards and, 1738
 PAL standards and, 1738
 presentation control information in, 1738
 read process in, 1737
 recordable DVD-R media, 1738
 standards for, 1737–38
 write process in, 1738
- digital video broadcasting, 2112, 2549, 2550
 broadband wireless access and, 321
 community antenna TV and, standards for, 524–527
 equalizers and, 91
 local multipoint distribution service and, 318, 320
- digital watermarking, 1077
 digital wrappers, signal quality monitoring, 2269
 digitization, waveform coding, 2830–34
 Dijkstra's algorithm, 550, 2208
 dimensionality, coding division multiple access, 458–461
- dipole antennas, 169, 180
 active antennas and, 48
 antenna arrays and, 142
 crossed drooping, 197, **197**
 directivity in, 1258
 gain in, 1258
 impedance, impedance matching in, 1258
 linear, 1257–58, **1257**
 radiation pattern in, 1257–58, **1258**
 television and FM broadcasting, 2517–36
- direct data domain least squares method, 71–73
 direct detection, wireless infrared communications, 2926
 direct detection receivers, optical transceivers, 1825
 direct digital frequency synthesizer, 447
 direct matrix inversion, blind multiuser detection, 298, 300, 306
- direct sequence CDMA, 458, 459, 1602
 adaptive receivers for spread-spectrum system and, 96, 97, 101, 104, 107
 Bluetooth and, 310
 in channel modeling, estimation, tracking, 409, 411
 chaotic systems and, 422, 428, **428**
 chirp modulation and, 445
 cochannel interference and, 455
 iterative detection algorithms for, 1196–1210
 media access control and, 1345
 multicarrier CDMA and, 1522, 1523
 multiple input/multiple output systems and, 1456
 packet rate adaptive mobile receivers and, 1886–87, 1886
 polyphase sequences and, 1975–82
 powerline communications and, 2003
 radio resource management (RRM) and, 2090, 2091–93
 shallow water acoustic networks and, 2209
 signature sequence for CDMA and, 2274, 2283, 2284
 spatiotemporal signal processing and, 2336
 Viterbi algorithms and, 1196–1210
 wireless multiuser communications systems and, 1608, 1614, 1615
- direct sequence spread spectrum, 1130–41, 2392–96, **2392**
 acoustic telemetry in, 23, 27
 blind multiuser detection and, 298
 diversity and, 733–734
 interference and, 1130–41
 multicarrier CDMA and, 1521, 1523
 shallow water acoustic networks and, 2216–17
 signature sequence for CDMA and, 2274
 in underwater acoustic communications, 41
 wireless communications, wireless LAN and, 1285, 2678, 2842–43, **2842**
- direct sequence ultrawideband radio, 2757
 direct sequency FSK, 1474
 direct solution algorithm, cyclic coding, 617
 direct video broadcast, broadband, 2671–73, **2672**

- directional antennas, 198, 1348
- directivity of antennas, 180, 185, **186**, 196
 - linear antennas and, 1258
 - loop antennas and, 1293–94
 - microstrip/microstrip patch antennas and, 1360–1361
 - active antennas and, 63
- directivity gain, in antenna arrays, 142
- discrete autoregressive model, traffic modeling, 1666, 1668
- discrete cosine transform
 - image and video coding and, 1039
 - image compression and, 1066, **1067**
 - image processing and, 1074, 1075
 - orthogonal transmultiplexers and, 1881, **1881**
 - vector quantization and, 2125–26
 - waveform coding and, 2837
 - wireless MPEG 4 videocommunications and, 2972–81
- discrete Fourier transform
 - adaptive equalizers and, 86
 - broadband wireless access and, 321
 - image processing and, 1074, 1075
 - orthogonal frequency division multiplexing and, 1871–72, 1944
 - orthogonal transmultiplexers and, 1880–85
 - simulation and, 2287, 2288
 - waveform coding and, 2837
- discrete Hadamard transform, 2837
- discrete logarithm problem, cryptography, 609–610
- discrete memoryless channels, information theory, 1113–14
- discrete multitone, 736–748, **738**
 - additive white Gaussian noise, 745
 - applications for, 746–747
 - asymmetric DSL and, 746–747, **747**
 - baseband and, 741–742
 - bit loading in, 745
 - digital signal processing and, 740–741
 - frequency division multiplexing and, 736–737, **737**
 - frequency domain equalization in, 745
 - guard interval in, 739–740, **739**
 - matrix notation in, 743–745
 - orthogonal frequency division multiplexing and, 736, 1878, 1944
 - quadrature amplitude modulation and, 737
 - Shannon or channel capacity in, 745–746
 - signal to noise ratio, 745
 - spectral properties of, 742–743, **743**
 - transmitters and receivers for, 740, **742**
 - very high speed DSL and, 2791–2801, **2792**, **2794**
- discrete time Fourier transform, digital filters, 690–691
- discrete time function, orthogonal transmultiplexers, 1880
- discrete time models, traffic modeling, 1667
- discrete time signals, digital filters, 687–689
- discrete Walsh transform, waveform coding, 2837
- discrete waveform/wavelet transform
 - image and video coding and, 1040
 - image compression and, 1067–68
 - image processing and, 1074, 1075
 - underwater acoustic communications, 37
- discrete-time, in channel modeling, estimation, tracking, 399–401
- discretionary access control, 1649
- dispatch radio services, 1478
- dispersion
 - fading and, 784
 - leaky wave antennas and, 1237, **1237**
 - microwave and, 2565
 - optical fiber and, 436, 1709, 1711, 1712–13
 - orthogonal frequency division multiplexing and, channel time, 1874
 - polarization mode (see polarization mode dispersion)
 - solitons and, 1764, 1765
 - wavelength division multiplexing and, 2869
- dispersion compensated optical fiber, 1712–13
- dispersion compensating devices, 1848
- dispersion compensating fiber, 1686, 1768, 1846
- dispersion compensating module, 1484
- dispersion management, optical fiber, 1686
- dispersion shifted fiber, 1711, 1714, 1845, 1848
- dispersive fade margin, microwave, 2565, **2566**
- distance routing effect algorithm for mobility, 2890
- distance vector multicast routing protocol, 1534
- distance vectors, 1534
- distorted Gaussian models, traffic modeling, 1670
- distortion
 - adaptive equalizers and, 79
 - amplitude modulation and, 134
 - blind equalizers and, 286
 - digital audio broadcasting and, 677
 - digital magnetic recording channel and, 1325–1326
 - image compression and, 1063
 - intersymbol interference and, 1157–62, **1158–61**
 - nonlinear (see also RF power amplifiers, nonlinear distortion in)
 - optical communications systems and, 1484–85
 - orthogonal frequency division multiplexing and, 1876
 - rate distortion theory and, 2069–80
- distortion bounds, compression, 640–641
- distortion rate function, 640–641, 2123
- distributed admission control, 118
- distributed Bellman–Ford algorithm, 2886
- distributed Bragg reflector laser, 1780–81, **1780**
- distributed COM, 725, 727
- distributed coordinated function, 1348
- distributed feedback laser, 1779, **1779**, **1780**
 - free space optics and, 1853–54
 - optical signal regeneration and, 1762
- distributed intelligent networks, 719–29, **722**, **726**
- distributed mesh feedback photonic AD conversion, 1967
- distributed protocols, media access control, 5, 1343
- distributed queue dual bus (DQDB), medium access control, 1558
- distributed queue multiple access, medium access control, 1558
- distributed routing, multimedia networks, 1566
- distribution, antenna arrays, synthesis by, 154
- distribution system, for wireless communications, wireless LAN, 1285
- diurnal variations in radiowave propagation, 2063, 2065
- divergence factors in radiowave propagation, 211
- diverging edge, in trellis coded modulation, 2627
- diversity, 371, 729–736
 - additive white Gaussian noise, 732, 733
 - applications for, 733–735
 - bit error rate and, 732, 733
 - cdma2000 and, 361, 367
 - channels and, 729
 - cochannel interference and, 456
 - combining techniques for, 730–733
 - cross correlation and, 729
 - fading and, 730–731, 787–788
 - gain and, 729
 - interleaving and, 733
 - IS95 cellular telephone standard and, 355–356
 - maximal ratio combining in, 731
 - microwave and, 2563–69
 - multipath and, 730–731
 - multiple input/multiple output systems and, 1455
 - optical fiber and, 735
 - optimal selection, 731
 - outage rates and, 729
 - quadrature amplitude modulation and, error probability and, 2050–52
 - radio resource management and, 2093
 - RAKE receivers and, 732, 734
 - satellite communications and, 1230–31
 - scanning, 731
 - signal to noise ratio, 731
 - space-time coding and, 2324
 - spatiotemporal signal processing and, 2333, 2334–36
 - tropospheric scatter communications and, 2693–95
 - wireless and, 2919–20
 - wireless multiuser communications systems and, 1603, 1608
 - wireless transceivers, multi-antenna and, 1583, 1584
- diversity gain, 1450–52, **1451**, **1452**, 2324
- diversity reception, in antennas for mobile communications, 190
- diversity techniques, 1481
- divisive methods in quantization, 2128
- DNA sequence analysis, and Viterbi algorithm, 2818
- DoCoMo, 392, 2193
- DOCSIS (see data over cable service interface specifications), 272
- Dolph–Chebyshev linear antenna arrays, 145–146, **147**, 187
- domain name servers, 548, 1913, 2199
- domain convolution, simulation, 2287
- dominant mode waveguides, 1390
- dominant path concept, indoor propagation models, 2020, **2021**
- doping for optical fiber, 1484
- Doppler effect, Doppler fading, Doppler spreading, 442
 - in acoustic modems for underwater communications, 18–19
 - acoustic telemetry in, 23
 - cellular communications channels and, 394, 395
 - in channel modeling, estimation, tracking, 410, 412, 413
 - chirp modulation and, 441
 - intelligent transportation systems and, 509–510
 - mobile radio communications and, 1481
 - multiple input/multiple output systems and, 1453
 - power control and, 1983
 - satellite communications and, 196, 197
 - shallow water acoustic networks and, 2207
 - simulation and, 2291
 - tropospheric scatter communications and, 2698–99
 - in underwater acoustic communications, 39–40, **39**
 - wireless and, 2916–18, **2917**, **2918**, 2916
 - wireless multiuser communications systems and, 1604
- Doppler frequency, 783–785, 2325
- Doppler power spectrum, wireless multiuser communications systems, 1604
- Doppler sensors, active antennas, 65
- double random phase encryption, 2132–33
- double sideband AM, 133
- double sideband suppressed carrier AM, 133–134, **133**, 140, **140**
- doubletalk, acoustic echo cancellation, 4, 11
- downlink, in satellite communications, 877, 1223, **1223**, 2115
- drift
 - ALOHA protocol and, analysis in, 129, **129**
 - frequency synthesizers and, 837
- DRIVE project in intelligent transportation systems, 503
- drive-response synchronization and chaos, 422, **422**
- driving point, optical modulators, 1746
- dropouts, digital magnetic recording channel, 1326
- DropTail algorithms, flow control, 1627, 1628, 1660
- DSA, 218
- dual beam antennas, 191, 194

- IATSA MTR scheduling in medium access control, 1558
- idle handoff, cdma2000, 366
- image and video coding, 1025–62
 additive white Gaussian noise, 1034
 advanced video coding in, 1054–55, **1055**
 analog to digital conversion in, 1026–27
 arithmetic coding in, 1032
 bit allocation and rate control in, 1044–46, **1045**
 block coding in, 1038–39
 color space in, 1026
 color subsampling in, 1026
 compression in, 1030
 compression ratios in, 1028–29
 context formation in, 1047
 differential PCM and, 1037–38
 discrete cosine transform in, 1039
 discrete waveform transform in, 1040
 entropy coding in, 1031–33
 error detection and correction in, 1030–31
 evaluating schemes for, 1028–29
 fractal compression in, 1044
 future research in, 1055–57
 generic model for, 1029–31, **1029**
 H.261 video codec in, 1051–52
 H.263 standards in, 1052–53
 Haar transform in, 1039
 Huffman coding in, 1031–32
 imaging in, 1025–26, **1026**
 interlaced scanning in, 1027
 JBIG standards for, 1049
 JPEG compression and, 1029, 1049–50, **1050**, 1211–18
 Karhunen-Loeve transform in, 1039
 lapped orthogonal transforms in, 1039
 Lempel-Ziv coding in, 1032–33
 linear transformations in, 1038–42
 mapping in, 1030
 Markov sources in, 1033
 motion estimation and compensation in, 1042–44, **1042**
 MPEG compression in, 1029, 1052, 1053–55, **1054**
 object-based coding in, 1057, **1057**
 post processing in, 1030–31, 1047–48
 pre processing in, 1047–48
 predictive coding in, 1033–34, **1034**, 1037–38, **1037**
 quantization in, 1026–27, 1030, 1035
 redundancy and irrelevancy in, 1027–28
 run length coding in, 1030, 1046
 scalable coding in, 1056–57
 scalar quantization in, 1035
 shape adaptive transforms in, 1041–42
 signal models for, 1034–35
 standards for, 1048–55
 subband decomposition in, 1039–41, **1041**
 symbol formation in, 1046–1047
 transcoding in, 1057
 uncompressed digital video in, 1027
 variable length coding in, 1030
 vector quantization in, 1030, 1035–37, **1036**
 vector transformations and, 1041
 video scanning and frame rate in, 1027
 visual texture coding in, 1050
 zero tree coding in, 1046–47
 zigzag scanning in, 1046
- image compression, 1062–73
- image processing, 1073–79
- image sampling and reconstruction, 1079–94, **1081–92**
- image source, in acoustic echo cancellation, 3
- image transmission, video, unequal error protection coding, 2764–65, **2765**
- iMode, 2193
- impedance, impedance matching
 active antennas and, 49, 50, **50**, 56
 antenna arrays and, 160
 antennas and, 169, 177, **177**, 180, 184, 186
 community antenna TV and, 524
 dipoles, 1258
 impedance, impedance matching
 linear antennas and, 1258
 loop antennas and, wave impedance in, 1293–95, **1292**
 microstrip/microstrip patch antennas and, 1358, 1359, **1360**, 1362, 1363, 1383
 powerline communications and, 2000
 television and FM broadcasting antennas, 2517–36
 waveguides and, 1395, **1395**, 1398–99, **1399**, 1401–03, **1403**
 waveguides and, 1398–99, **1399**
- impersonation attack, 219, 222
- importance density function, in speech coding/synthesis, 2365–66, **2366**

- impulsive noise, 2402–2420
- IMT2000, 358, 392, 1094–1108, 2873–74
 admission control and, 126
 advanced mobile phone service and, 1095–1108
 architecture for, 1101–06
 cdma2000 and, 1096–1108
 cell planning in wireless networks and, 369, **386**
 cellular communications channels and, 397
 code division multiple access, 1095–1108
 context and evolutionary paths of, 1097–99
 core network for, 1102–04
 customized applications of mobile network enhanced logic and, 1101–08
 digital enhanced cordless telephony and, 1096–1108
 enhanced data for GSM evolution and, 1096–1108
 future of, 1106–07
 global system for mobile and, 1095–1108
 harmonization efforts in, 1097
 history and development of, 1097–99
 IP networks and, 1103
 license assignment and economic implications of, 1106
 migration paths for, 1098–99, **1100**
 mobile IP and, 1103
 open service architecture for, 1100–01
 Parlay and, 1100
 quality of service, 1099–1101, 1103
 radio access network for, 1101–02, **1102**
 radio interface for, 1095–96
 satellite communications and, 2116
 standards for, 1095–97
 synchronous CDMA and, 1096
 terminals and services for, 1099–1101
 terminals, 1101, **1101**
 time division multiple access and, 1095–1108
 universal mobile telecommunications system and, 1096–1108
 virtual home environment for, 1101
 wideband CDMA and, 1096, 1104–05
 wireless application protocol and, 1100
 wireless IP telephony and, 2932–41
- in band signaling, transport protocols for optical networks, 2618

mean distance ordered partial search, vector quantization, 2126

- mean effective gain, antenna for mobile communications, 192–193
- mean opinion score, in speech coding/synthesis, 1179, 1305, 2352, **2353**, 2819–20
- mean removed vector quantization, 2127
- mean squared error algorithm
 - adaptive antenna arrays and, 187
 - blind multiuser detection and, 303
 - in channel modeling, estimation, tracking, 413, 415
 - equalizers and, 81, 83–84, **84**, 86, 88
 - fading and, 781
 - rate distortion theory and, 2069–80
 - spatiotemporal signal processing and, 2338–39, **2339**
 - speech coding/synthesis and, 2347–48
 - synchronization and, 2475
 - transform coding and, 2593
 - in underwater acoustic communications, 42
- meander patch antenna, 193, 194, **194**
- measurement-based admission control, 118, 1656
- mechanical memories, 1319
- media access control, 15, 547, 549, 1342–49
 - ADAPT protocol and, 1348
 - adaptive round robin and earliest available time scheduling in, 1556, 1559
 - allocation-based protocols in, 1343, 1344–46, 1344
 - ALOHA protocols and, 1346, 1347, 1552, 1553, 1559
 - application level data units and, 1553
 - ATM and, 2907–09
 - backoff schemes and, 1346
 - bucket credit weighted algorithms in, 1556
 - busy tone multiple access and, 1347
 - cable modems and, 324, 334–335
 - carrier sense multiple access and, 346, 1346–47
 - CATA protocol and, 0, 1348
 - cdma2000 and, 359, 363–365
 - cellular digital packet data and, 9, 1347
 - centralized vs. distributed protocols in, 5, 1343
 - channel available time table in, 1554
 - classification of protocols using, 1342–44
 - clear to send in, 1348
 - code division multiple access and, 1343–45, 1348
 - collision free protocols for, 1557
 - connectivity and, 1343
 - contention-based protocols in, 1343, 1346–47
 - credit weighted algorithms in, 1556
 - cyclic reservation multiple access and, 1558
 - deterministically guaranteed service and, 1556
 - direct sequence CDMA and, 7, 1345
 - directional antenna and, 1348
 - distributed coordinated function in, 1348
 - distributed queue dual bus and, 1558
 - distributed queue multiple access in, 1558
 - dynamic allocation schemes and, 1553
 - dynamic time wavelength division multiple access and, 1552
 - earliest available time scheduling in, 1554
 - energy efficient, 0, 1348
 - Ethernet and, 1347, 1501
 - fair distributed queue in, 1558
 - FairNet and, 1558
 - FatMAC protocol and, 1553
 - fiber distributed data interface and, 1346
 - fixed assignment in, 1552
 - fixed priority oriented demand assignment in, 1347
 - flying target algorithm in, 1557
 - frequency division multiple access and, 1344
 - frequency domain protocols in, 1342–43
 - frequency hopping CDMA and, 1344–45, **1345**
 - global system for mobile and, 1343, 1344
 - graceful degradation and, 1345
 - graph coloring problem and, 1344
 - hidden and exposed terminal problems in, 1343, 1347
 - HIPERLAN and, 1348
 - hop in, 1344
 - hybrid domain protocols in, 1343
 - hybrid optical networks and, 1559
 - hybrid protocols in, 1347
 - hybrid TDM and, 1553
 - IATSAMTR scheduling in, 1558
 - interframe spacing and, 1347
 - KTMTR scheduling and, 1558
 - LiteMAC protocol and, 1553
 - local area networks and, 1281–82
 - local multipoint distribution services and, 1269
 - maximum laxity first scheduling in, 1555
 - Meta-MAC protocol and, 1348
 - minimum laxity first with time tolerance scheduling in, 1555–56
 - MPEG compression and, 1558, 1559
 - multimedia applications and, 1558–60, **1559**
 - multimedia wavelength division multiple access and, 1558
 - multiple access collision avoidance and, 1347–48
 - near far problem in, 1343
 - nonpretransmission coordination protocols in, 1552
 - optical networks and, 1551–62, 1716
 - packet demand assignment multiple access in, 1347
 - packet transmission and, 1551–55
 - partial fixed assignment protocols in, 1552
 - physical link characteristics and, 1343
 - point coordination function and, 1348
 - polling in, centralized vs. distributed, 1345–46
 - powerline communications and, 1995, 2003–04
 - pretransmission coordination protocols in, 1552–53
 - priority index algorithm in, 1557
 - propagation time and, 1343
 - protocol threading in, 1348
 - quality of service and, 1556–59
 - random access protocols in, 1552
 - random delay and, 1346
 - real time service and, 1555–58
 - receiver available time table in, 1554, 1555
 - receiver oriented earliest available time scheduling in, 1554–55
 - receiver oriented protocols using, for variable length messages, 1554
 - reservation protocol and, 1558
 - reservation-based protocols in, 1343, 1347–48, 1552–54
 - satellite communications and, 879
 - sensor networks and, 1348
 - shallow water acoustic networks and, 2208, 2209–10, 2215–17, **2216**
 - spatial reuse and, 1344
 - splitting algorithms and, 1347
 - spread spectrum and, 1343, 1344–45
 - statistically guaranteed service and, 1556–58
 - synchronous round robin with reservation in, 1557
 - throughput and, 1344
 - time deterministic time/wavelength division multiple access in, 1555
 - time division multiple access and, 1343, 1344, 1347
 - time division multiplexing and, 1552, 1553
 - time division WDMA and, 1553
 - time domain protocols in, slotted and unslotted, 1342
 - time spread multiple access in, 1348
 - token ring and, 1345–46
 - transmitter scheduling algorithm in, 1557
 - tree algorithms and, 1347
 - validated queue algorithm in, 1556
 - variable length message transmission and, 1551–55
 - video on demand and, 1558
 - wavelength division multiple access and, 1558
 - wavelength division multiplexing and, 1551–52, **1551**, 2842
 - wireless communications, wireless LAN and, 1285–87, 1343, 2942
 - wireless packet data and, 2982
 - wireless sensor networks and, 2993–94
 - media gateways, session initiation protocol, 2198
 - media independent interface, Ethernet, 1502, 1506, 1507
 - media noise, digital magnetic recording channel, 1325
 - medium access unit, Ethernet, 1506
 - medium dependent interface, Ethernet, 1508, **1509**, 1508
 - medium earth orbit satellite, 196, **196**, 1223, 1224, 1231, 1232, 1249, 2112
 - medium frequency, 208, 2059–60
 - medium wave, 1477
 - MEGACO/H.248 session initiation protocol, 2198
 - mel scale, automatic speech recognition, 2373
 - mel scale frequency cepstral coefficients, in automatic speech recognition, 2373, 2382
 - memory
 - constrained coding techniques for data storage and, 575
 - minimum shift keying and, 1457, 1458
 - neural networks and, 1677
 - optical, 1733–41, **1734**
 - transport protocols for optical networks and, 2620
 - memory nonlinearities, simulation, 2290
 - memory order, in sequential decoding of convolutional coding, 2141
 - memory requirements of quantization, 2128
 - memoryless modulation
 - pulse amplitude modulation and, 2024
 - sequential decoding of convolutional coding and, 2144
 - serially concatenated coding and, 2173
 - memoryless nonlinearities, in simulation, 2289–90
 - memoryless source, in compression, 632, 633–634, 641
 - Menger's theorem, 1635
 - merging bits, merging rules, constrained coding techniques for data storage, 576
 - merging edge, trellis coded modulation, 2627
 - merit factors
 - Golay complementary sequences and, 895
 - peak to average power ratio and, 1951
 - mesh networks
 - cycle covers and, 1638–39, **1638**
 - fault tolerance and, 1637–39, **1638**, **1639**
 - reliability and, 1637–39, **1638**, **1639**
 - message authentication coding, 218, 613
 - message passing, product coding, 2011
 - message signal, amplitude modulation, 132, 133
 - messages, protocols, 538–556
 - metal organic vapor phase epitaxy process, 1778
 - metal oxide semiconductor FET active antenna, 57–58, **57**, **58**
 - metal semiconductor FET active antenna, 57–58, **57**, **58**
 - metal semiconductor metal photodetectors, 1001–02
 - Meta-MAC protocol, 1348
 - method of moments
 - adaptive antenna arrays and, 68
 - antenna arrays and, 165
 - antenna modeling and, 173, 174, 175
 - waveguide and, 1420
 - metropolitan area exchanges, IP networks, 268
 - metropolitan area networks, 2461
 - Ethernet and, 1512
 - fault tolerance and, 1632
 - HiperMAN and, 320
 - local multipoint distribution services and, 1268
 - multicasting and, 1529
 - optical fiber and, 1714, 1808
 - optical fiber systems and, 1840

 - microelectromechanical systems, 1349–56
 - cellular digital packet data and, 1350
 - code division multiple access and, 1350
 - deep reactive ion etching in, 1352
 - devices, circuits, systems using, 1352–55
 - digital European cordless telecommunications and, 1350
 - fabrication techniques for, fundamentals of, 1350–52, **1351**
 - general packet radio service and, 1350
 - global system for mobile and, 1350
 - Internet protocol and, 1350
 - micromachining in, 1351, **1352**
 - optical cross connects/switches and, 1705, **1705**, 1784, 1785, 1793–96, **1794**, **1795**
 - optical multiplexing and demultiplexing and, 1758
 - radio frequency components and, 1350
 - sacrificial and structural layers in, 1351
 - stiction in, 1351
 - wireless sensor networks and, 2990–96

- microflow, in flow control, traffic management, 1653
microfluidoptical crossconnects, 1704, **1704**
micromachining, microelectromechanical systems, 1351–52, **1352**
microphone transducers (acoustic), 34, **34**
microstrip end launcher
 waveguide and, 1400, **1400**, **1404**, **1405**, 1400
 waveguide and, 1401–05, **1401**, **1402**, 1401
microstrip E-plan probe, 1399, **1399**, 1399
microstrip feed line, 51–52, **52**, 62, **62**, 1362–63, **1362**
microstrip/microstrip patch or line antenna, 180, 184, 187, 193, 197, **197**, 199, 1356–80, **1357**
 antenna arrays and, 142, 152, **152**
 aperture coupled microstrip feed line for, 1362–63, **1363**
 aperture coupled type, 1368–70, **1371**
 arrays of, 1371–77, 1380–90
 bandwidth in, 1360, 1364–70
 blindness in, 1371, 1376, 1388
 cavity models of, 1357
 coaxial feed for, 1361–62, **1362**
 comb line arrays in, 1374, **1376**
 combination feeds in, 1383–84, **1383**
 configuration and shapes used in, 1361, **1362**
 coplanar microstrip feed line for, 1362–63, **1362**
 coplanar parasitic elements in, 1367–68, **1368**
 design of, 1358–61
 development of, 1356–57
 dielectric substrate in, 1358, **1360**, 1361, 1363, 1365
 directivity in, 1360–61
 electrical characteristics of, 1357–61, **1357**
 element length in, 1359, **1359**
 element width in, 1358–59, **1359**
 fabrication of, tolerances and impact of, 1361, **1361**
 FEDCOMA and FEGCOMA configurations in, **1368–70**
 feed methods for, 1361–63
 feeds for, 1373–74, **1373**, **1374**, 1380, 1383–84, **1383**
 fixed-beam planar array of, 1386–87, **1386**, **1387**
 gain in, 1360–61, **1361**, 1380
 half power beamwidth for, 1358
 impedance matching in, 1363, 1383
 input impedance in, 1358, 1359, **1360**, 1362
 leaky wave antenna and, 1241–43, **1243**
 linear arrays of, parallel and serial fed, 1373–85, **1373–76**, **1381–83**
 losses associated with, 1359–60, **1360**
 microstrip feed line for, 1362–63, **1362**
 millimeter wave antenna and, 1429, **1429**, **1430**
 multiresonator type, 1367–70
 mutual coupling in, 1370–71, **1371**, **1372**, **1373**
 narrowband configuration of, 1357
 nonresonant methods for bandwidth enhancement in, 1366–67
 phased array of, 1384–85, **1384**, **1385**
 planar arrays of, 1374–75, **1377**, 1385–89, **1386**, **1387**
 polarization (linear, circular) properties in, 1363–64, **1363**, **1364**
 printed circuit board for, 1380
 pros and cons of, 1357
 proximity coupled microstrip feed line for, 1362–63, **1363**
 quality factor in, 1357, 1359–60, 1364
 radiation patterns in, 1357–58, **1358**, 1359
 reflectarray type, 1387, **1387**
 resonant frequency/resonant dimension of, 1359, **1359**, 1361, **1361**
 scanning arrays of, 1375–77, 1384–85, 1387–89
 single patch bandwidth in, 1365–66, **1365**, **1366**
 spiders in, 1388
 stacked type, 1367, **1367**
 suspended type, 1365–66
 transmission line models of, 1357
 voltage standing wave ratio in, 1360, 1363, 1366, **1367**
 waveguide arrays of, 1373–74
 Wilkinson dividers for, 1373, 1382
microtrack model, magnetic recording systems, 2252–53, **2252**
microwave, 208, 1706, 2179, 2555–72
 absorption in, 2560
 active antenna and, 47–48, 49, 65
 adaptive equalizers and, 2569–70
 anomalous propagation in, 2559–60
 antenna for, 179, 180, 2567
 atmospheric effects and, 2558–60, **2559**
 attenuation, 2560
 automatic gain control and, 2567
 bit error rate (BER) in, 2565–67, **2566**
 broadband wireless access and, 317
 channel models for, 2564–65
 community antenna TV and, 513
 digital elevation models for, 2561
 digital radio design and, 2567–70, **2568**
 digital terrain elevation data and, 2561
 dispersion in, 2565
 dispersive fade margin in, 2565, **2566**
 diversity and, 2563–66, 2567–69
 equalization and, 2565
 fading in, 2562–65, **2562**, 2571
 free space loss in, 2556
 frequency allocation in, 2566–67
 Fresnel zones in, 2557–58, **2558**
 gain in, 2570–71
 interference and, 2566–67
 inverse bending (earth bulge) in, 2559
 land use/land clutter in, 2561
 leaky wave antenna and, 1236
 line of sight transmission and, 2555–72
 multipath in, 2562–65, **2562**
 non return to zero in, 2567
 parabolic and reflector antenna and, 1927–28
 path profiles for, 2560–62, **2561**
 protection systems in, 2569
 quadrature amplitude modulation and, 2569, **2570**
 radio link calculations for, 2570–71
 rain attenuation in, 2560
 receivers for, 2567–70, **2568**
 reflection in, 2556–57, **2557**
 refraction and, 2558–60, **2559**
 signal to noise ratio, 2567, 2571
 subrefraction in, 2559
 superrefraction in, 2559–60
 terrain effects in, 2556–58
 transmitters for, 2567–70, **2568**
 traveling wave tubes and, 2567
 waveguide for, 1390–1423
 microwave multipoint distribution service, 317
 microwave waveguide (see waveguide)
 midamble
 adaptive equalizers and, 90
 packet rate adaptive mobile receivers and, 1899
 Middleton model, in impulsive noise, 2409–10, 2416
 Mie scatter, free space optics, 1855–57
 Military Amateur Radio Service, 1478
 military applications for antenna, 169
 military communications, 1477
 military use of wireless LANs, 2680–82
 Miller coding, in constrained coding techniques for data storage, 576
 Miller Rabin cryptography, 614–615
 millimeter wave antennas, 1423–33
 active integrated antenna, 1429–31, **1430**, **1431**
 amplitude modulation and, 1425
 application of millimeter waves and, 1425
 bandwidth in, 1425
 beam steering type, 1431, **1432**
 efficiency in, 1425
 frequency and, 1423–25, **1424**
 gain in, 1425
 horn type, 1425, **1425**, 1427–28, **1427**
 leaky wave antenna and, 1236
 leaky wave, 1428, 1428
 local multipoint distribution services in, 1268–79
 losses in, 1425
 microstrip/microstrip patch antenna and, 1429, **1429**, **1430**
 millimeter waves defined for, 1423–25, **1424**
 nonradiative dielectric waveguide and, 1428, 1428
 optically controlled, 1431, **1431**
 periodic dielectric type, 1428, **1428**
 planar AIA in, 1430–31, **1431**
 printed circuit type, 1428–29, **1429**
 radiation patterns in, 1425
 reflector and lens type, 1425–26, **1426**, **1427**
 slotted waveguide type, 1428, **1429**
 waveguide based, 1426–28, **1427**, **1428**
 waveguide derived, 1427–28
 wavelength in, 1423
 millimeter wave propagation, 1270–72, 1423–25, 1424, 1433–50
 absorption and emission in, 1270, **1270**, 1436–37, 1439
 absorption of, in clear air, 1270, **1270**
 angle error in, 1435
 applications for, 1434
 atmospheric effects on, 1434–43
 atmospheric particulate effects and, 1439–43
 attenuation in, 1443–45, **1444**, 1445–48, **1446**, **1447**
 bandwidth and, 1434
 bending in, 1435
 Brewster angle in, 1438
 cloud, fog, haze attenuation in, 1442–43, **1443**
 depolarization in, 1272, 1439–40, 1445
 diffraction in, 1438–39, 1445
 ducting in, 1435, 1445
 Earth-space transmission paths for, 1445
 emission in, 1436–37, 1445–46
 fog attenuation in, 1272
 Fresnel zone and, 1438
 global positioning system and, 1436
 Kirchhoff's law and, 1437
 laser vs., 1449
 line of sight transmission in, 1443–45
 maritime communication systems using, 1434
 multipath interference and, 1434, 1445
 multipath interference in, 1438
 oxygen and absorption in, 1437, **1437**
 propagation effects on, 1433–34
 radio relay systems using, 1434
 rain attenuation and, 1270–72, 1440–45, **1440**, **1441**
 Rayleigh scattering in, 1271
 refraction and refractive index in, 1434–36, **1435**, 1445
 sand and dust attenuation, 1443
 satellite communication systems and, 1434
 scattering in, 1271, 1434, 1437–39, 1445
 scintillations in, 1436
 sleet, snow, hail attenuation in, 1442
 subrefraction in, 1435–36
 terrain scatter and diffraction in, 1445
 time delay in, 1436
 transmission paths for, 1443–48
 water vapor and absorption in, 1437, **1437**
 waveguide and, 1434
 window regions in, 1433, 1434
 Millington method and groundwave propagation, 2060
 Min-Idle batching, 235
 miniaturization, waveguide, 1405–11, **1406**
 minicells, 376
 minimal encoders, convolutional coding, 600
 minimal polynomials, BCH coding, binary, 242–243
 minimax criterion equalizers, 81, 82–83
 minimum cell rate, ATM, 266, 552
 minimum cost tree, ad hoc wireless networks, 2891
 minimum distance algorithm, 2056, 2142
 minimum functions, BCH coding, binary, 242
 minimum laxity first with time tolerance scheduling, 1555–56
 minimum likelihood, quadrature amplitude modulation, 2054
 minimum mean square error algorithm (see also Wiener filters), 1116
 blind equalizers and, 292
 blind multiuser detection and, 298–307
 broadband wireless access and, 321
 code division multiple access and, 463–464
 magnetic recording systems and, 2261
 magnetic storage and, 1329
 maximum likelihood estimation and, 1341
 multiple input/multiple output systems and, 1455
 packet rate adaptive mobile receivers and, 1886–1903

- minimum mean square error algorithm (see also Wiener filters) (*continued*)
 - predistortion/compensation in RF power amplifiers and, predistortion in, 532–533
 - tapped delay line equalizers and, 1690, 1691, 1692
 - wireless multiuser communications systems and, 1616–17
 - wireless transceivers, multi-antenna and, 1588
- minimum output energy detector, 301
- minimum reuse routing, in routing and wavelength assignment in WDM, 2103
- minimum shift keying, 584–593, 1457–77
 - additive white Gaussian noise and, 1468
 - antipodal signaling in, 1457
 - bandwidth and, 1457
 - binary frequency shift keying and, 1457
 - coherent detection in, 1468–70, **1469**
 - continuous phase frequency shift keying and, 593–598, 1457
 - continuous phase modulation and, 1457–59, **1458**, 2182
 - continuous shift keying and, 1473–74
 - cross coupled IQ transmitter for, 1467, **1467**
 - decoder for, 1462–63
 - differentially coherent detection in, 1470–71, **1471**
 - direct sequence FSK and, 1474
 - duobinary encoder in, 1474, **1475**
 - frequency shift in, 1457
 - full and partial response schemes in, 1457, 1458
 - generalized, 1458
 - generalized, 1457
 - inphase-quadrature signal in, 1457, 1463, 1459–61, **1460**, **1461**, 1472
 - instantaneous frequency pulse in, 1458
 - intersymbol interference and, 1466–67
 - maximum a posteriori estimation and, 1472, **1473**–74

 - distortion in, 1484–85
 - erbium doped fiber amplifier in, 1484
 - four-wave mixing in, 1490
 - Gordon-Haus effect in, 1490
 - interference in, 1484
 - Jones vectors and Jones matrix in, 1492
 - multiplexing/demultiplexing in, 1484
 - noise and, 1484–85, **1486**
 - noise figure in, 1485
 - nonlinear Schrodinger equation in, 1488, 1489, 1491
 - optical birefringence in, 1492
 - polarization and, 1484–85, 1491–93
 - polarization dependent loss in, 1493
 - polarization mode dispersion in, 1492–93
 - principal states of polarization in, 1492
 - Raman scattering in, 1491
 - receivers (coherent receivers) for, 1484, 1486–88, **1486**, **1487**, **1488**
 - scattering in, 1491
 - self-phase modulation and, 1489, **1489**
 - signal to noise ratio in, 1485–87, 1493
 - spectral efficiency of, 1488
 - transmitters for, 1484, 1488–91, **1489**, **1491**
 - wavelength division multiplexing and, 1490–91, **1490**, 1484–85, **1485**
- modems, 539, 1494–1501
 - acoustic telemetry in, 23–24
 - amplitude modulation and, 1497
 - analog to digital conversion in, 1495
 - asynchronous mode in, 1495
 - baud in, 1496
 - bit rate in, 1496
 - cable (see cable modems)
 - compression in, 1496
 - cyclic redundancy check in, 1495
 - data communication equipment and, 1495, 1496
 - data terminal equipment and, 1495, 1496
 - differential PSK and, 1497
 - digital subscriber line and, 1499–1500
 - digital to analog conversion in, 1495
 - DOCSIS and, 1500
 - fax transmission using, 1499
 - file transfer/data transfer in, 1497
 - flow control in, 1496–97
 - forward error correction in, 1497
 - frequency modulation and, 1497
 - frequency shift keying and, 1497, 1498
 - H.324 standard and, 919–920
 - high frequency communications and, 951, 952–955
 - home area networks and, 2687
 - integrated services digital network and, 1495
 - Internet service providers and, 1498–99

modems (*continued*)

- link access protocol-modem protocol in, 1496
- MNP compression in, 1496
- modulation techniques in, 1497–99
- Naval Undersea Warfare Center range-based modem in, 25–26, **25**
- operation of, 1495–97
- parallel vs. serial transmission and, 1494–95
- phase shift keying and, 1497
- POTS splitters for, 1500
- public switched telephone network and, 1495
- pulse amplitude modulation and, 2022
- pulse coding modulation and, 1497
- quadrature amplitude modulation and, 1497, 1498
- retraining in, 1498
- RS-232 connections in, 1495
- RTS/CTS flow control in, 1497
- shell mapping and, 2222, 2227
- software radio and, 2308
- speeds of, 1495–96
- standards for, 1497–99
- start/stop transmission in, 1495
- symbols in communication and, 1497
- synchronous mode in, 1495
- telesonar, 2215
- trellis coded modulation and, 1497, 1498, 2632, **2632, 2633**
- two dimensional encoding, 1497
- underwater communications (see acoustic modems, underwater communications)
- universal asynchronous receiver/transmitter and, 1495
- V.34, 2640
- V.42bis compression in, 1496
- V.90, 2770–79, **2771**
- very high speed DSL and, 2779
- Vxx standards for, 1498–99
- X2 protocol for, 1498, 1499
- Xmodem, Ymodem, Zmodem in, 1497
- Xon/Xoff mechanisms in, 1496
- modem, modespacing, lasers, 1777
- modification attacks, 1151
- modified frequency modulation, 576, 1327
- modified prime coding, optical synchronous CDMA systems, 1812, 1819–21
- modified syndromes for decoding, in BCH and Reed–Solomon coding, 259–260, 469–470, 469
- MODTRAN database and calculations, free space optics, 1856–57
- modulation, 16, 132–141, 371, 1477–78, 2179
 - in acoustic modems for underwater communications, 19
 - acoustic telemetry in, 23, 24
 - active antenna and, 49
 - amplitude (see amplitude modulation)
 - bit interleaved coded modulation and, 275–286, **275, 277**
 - bit interval in, 7, 1335
 - carrierless amplitude and phase, 336–339, **337, 338**
 - cdma2000 and, 362
 - CDROM and, 1735
 - chaotic systems and, 422, 423, **423**
 - chirp, 440–448
 - continuous phase coded, 584–593
 - continuous phase frequency shift keying and, 593–598
 - continuous phase modulation and, 593–598
 - demodulation process and (see also demodulation), 1335
 - digital audio broadcasting and, 684
 - digital phase modulation and, 709–719
 - duobinary frequency shift keying, 585
 - free space optics and, 1851
 - frequency modulation in, 807–825
 - frequency shift keying and, 593
 - Gaussian minimum shift keying and, 584–593
 - generalized tamed frequency modulation and, 585
 - global system for mobile and, 913
 - high frequency communications and, 954
 - IS95 cellular telephone standard and, 350, **351, 353, 354**
 - lasers and, 1779, 1781
 - leaky wave antenna and, 1241
 - magnetic recording systems and, 2249–51, 2253–58
 - M-ary frequency shift keying and, 1335
 - M-ary time shift keying and, 1335
 - matched filter demodulation and, 1335–38, **1336**
 - minimum shift keying and, 584–598, 1457–77
 - modems and, 1497–99
 - multiple input/multiple output systems and, 1455–56
 - optical fiber and, 1708, 1825–32, 1848
 - optical modulators and, 1741–48
 - optical synchronous CDMA systems and, 1809, 1813
 - partial response signals and, 1928, 1933–34
 - permutation coding and, 1953
 - phase modulation in, 807–825
 - phase shift keying and, 593, 1335
 - power spectra of digitally modulated signals, 1988–95
 - powerline communications and, 1995, 2003
 - predistortion/compensation in RF power amplifiers and, 530
 - pulse amplitude modulation and, 1335, 2021–30
 - pulse position modulation, 2030–42, **2031**
 - quadrature amplitude modulation, 1335, 2043–58, **2043**
 - quadrature phase shift keying and, 589
 - raised cosine modulation and, 585
 - satellite communications and, 1225, **1225**
 - satellite onboard processing and, de- and remodulation in, 480–482, **480, 481**
 - spectrally raised cosine modulation and, 585
 - speech coding/synthesis and, 2368
 - symbols and symbol duration in, 1335
 - tamed frequency modulation and, 584–593
 - terrestrial digital TV and, 2549–50
 - trellis coded modulation and, 590
 - trellis coding and, 2635
 - in underwater acoustic communications, 40–41, 45–46
 - wideband CDMA and, 2878
 - wireless infrared communications and, 2927–27
 - wireless multiuser communications systems and, 1610, 1611–12
- modulation coding (MC), 570, 573, 1326
- modulation index, in minimum shift keying, 1457
- modulation transfer function, constrained coding techniques for data storage, 572–573, **572**
- MOE algorithm, adaptive receivers for spread-spectrum system, 109
- Molnya orbit, 1250
- moment methods, 403, 406–407
- monitoring signal quality (see signal quality monitoring)
- monofractal models, traffic modeling, 1669
- monopole antenna, 142, 193, **193, 193**
- monotonic transformation, maximum likelihood estimation, 1339
- Monte Carlo simulation, 422, 2285, 2291–94, 2916
- Moore's law, 263
- morphological operators, in image processing, 1074
- motion estimation and compensation, 1042–44, **1042**
- Motley–Keenan model, indoor propagation models, 2016, **2016**
- moving average filters, in channel modeling, estimation, tracking, 412, 413
- moving coil electrodynamic loudspeaker transducers (acoustic), 34, **34**
- MP3 audio compression, 1319
- MPEG compression, 232
- BISDN and, 263
- cable modems and, 324, 330
- community antenna TV and, 522, 525
- digital audio broadcasting and, 682–683
- digital versatile disc and, 1738
- image and video coding and, 1029, 1052, 1053–55, **1054**
- magnetic storage and, 1319
- medium access control and, 1558, 1559
- multimedia over digital subscriber line and, 1571
- piggybacking in, 232–233, **232**
- satellite communications and, 880
- speech coding/synthesis and, 2356, 2819
- streaming video and, 2435–36
- terrestrial digital TV and, 2552–53, **2553**
- traffic modeling and, 1672
- video, unequal error protection coding and, 2765–66
- vocoders and, 2819
- wireless MPEG 4 videocommunications and, 2972–81
- MSAT satellite communication, 196, 198
- Muller matrix, optical fiber, 436
- multiaccess interference, 2215
- multiaddress set claim protocol, 1536–37, **1536**
- multiband excitation coding, speech coding/synthesis, 2351
- multibase ALOHA, 131
- multibeam phased arrays, 1513–21, **1514**
 - analog to digital conversion and, 1520, 1521
 - applications for, 1519
 - bandwidth and, 1518
 - beam steering using, 1519, 1520
 - beamforming in, 1517, **1517, 1518**, 1520–21, **1520**
 - beamwidth in, 1517
 - Butler beamformer using, 1517, **1518**
 - coding division multiplexing in, 1514
 - cost of, 1518
 - element arrangement in, 1513–14
 - far field in, 1514
 - Fraunhofer region and, 1514
 - frequency reuse and, 1514
 - Fresnel region in, 1514
 - future developments for, 1521
 - gain in, 1517
 - interference cancellation in, 1519, 1520–21
 - Iridium and, 1519
 - linear arrays in, single and multibeam, 1514–15, **1515, 1516**
 - mutual coupling in, 1516
 - near field in, 1514
 - one dimensional, 1513
 - overlap of beams in, 1516
 - polarization in, 1514
 - satellite communications and, 1519
 - scan loss in, 1517
 - sensitivity and, 1518–19
 - sidelobe level in, 1517
 - signal to noise ratio and, 1519
 - simultaneous users and, transmit and receive limits, 1517
 - time division multiplexing in, 1514
 - tracking and data relay satellite using, 1519
 - two dimensional, 1513, 1515–17, **1516, 1517**
- multicarrier CDMA, 1521–28
 - additive white Gaussian noise and, 1522, 1526
 - comparison of various flavors of, 1527–28
 - direct sequence CDMA and, 1522, 1523
 - direct sequence spread spectrum and, 1521, 1523
 - equal gain combining detector in, 1527
 - fast Fourier transforms in, 1522
 - frequency division multiplexing and, 1522
 - frequency domain coding in, 1524
 - interference in, 1527
 - maximal ratio combining detector in, 1527
 - maximum likelihood detector in, 1527
 - multicarrier direct sequence CDMA, 1524
 - multicarrier modulation in, 1521–28, **1522**
 - multitone CDMA and, 1525
 - multiuser interference and, 1527
 - multiuser OFDM and, 1527–28
 - orthogonal frequency division multiplexing in, 1521, 1523, 1524, 1525–28, **1526**
 - orthogonality restoring detector in, 1527
 - RAKE receivers and, 1523–24, **1523**
 - spreading sequence in, 1523
 - transmitter and receiver for, 1522–25, **1522, 1524, 1525**
 - Walsh–Hadamard coding in, 1526
- multicarrier direct sequence CDMA, 1524
- multicarrier frequency division duplex, 2116
- multicarrier modulation
 - asymmetric DSL and, 1572
 - multicarrier CDMA and, 1521–28, **1522**
- multicarrier transmission, synchronization, 2481–82
- multicast algorithms, 1529–38
- multicast backbone, 1535, 2432
- multicast capable OXCs, 2104
- multicast open shortest path first, 1533–34, **1534**

- multicast routing, wavelength assignment, 2104–05
- multicast source discovery protocol, 1535
- multicast tree, 1530, **1530**, 1530
- multicasting, 2615
 - ad hoc wireless networks and, 2890–93
 - border gateway multicast protocol and, 1535, 1536
 - border gateway protocol and, 1535
 - core-based tree in, 1535
 - distance vector multicast routing protocol in, 1534
 - Ethernet and, 1529–30
 - forwarding in, 1532
 - group communication and, 1529–31, **1529**, **1530**
 - interdomain routing protocols in, 1535–37
 - Internet and, 1531–32, **1531**
 - intradomain routing and, 1533–35
 - IP addresses in, 1531
 - IP networks and, 1531
 - KMB algorithm in, 1533
 - Kruskal's algorithm in, 1532
 - local area networks and, 1529–32
 - MAC addresses and, 1529, 1531–32, **1532**
 - metropolitan area networks and, 1529
 - minimum spanning tree problem in, 1532
 - multiaddress set claim protocol and, 1536–37, **1536**
 - multicast backbone and, 1535
 - multicast open shortest path first in, 1533–34, **1534**
 - multicast source discovery protocol in, 1535
 - multicast tree in, 1530, **1530**
 - multiprotocol extension to BGP4, 1535
 - parent and child targets in, 1536
 - point to point networks and, 1530–31, **1530**
 - Prim's algorithm in, 1532
 - protocol independent multicast sparse mode in, 1534–35
 - reachability in, 1536
 - reverse shortest path tree and, 1534
 - routers and, 1531, **1531**, 1533
 - routing information protocol and, 1534
 - security and, 1154–55
 - shared-medium networks and, 1529–30
 - Steiner tree problem in, 1532–33
 - target lists in, 1536
 - TM algorithm and, 1533
 - token ring and, 1529
 - unicast vs., 1530
 - wavelength division multiplexing and, 655
 - wide area networks and, 1532
- multicasting core extraction distributed ad hoc routing, 2892–93
- multicavity optical filters, 1725
- multichannel ALOHA, 130
- multichannel multipoint distribution services, 2655, 2671
- multicopy ALOHA, 130
- multidimensional coding, 1538–51
 - additive white Gaussian noise and, 1542–43, 1542, 1545–47, **1546**
 - algebraic replicas in, 1541–42
 - bit error rate, 1545–48, **1548**
 - burst errors and, 1540–41, 1544–48
 - bursty channels and, 1547–48

 decoding in, 254–261, 469–470, 622–626
- deep space telecommunications and, 629
- elementary symmetric functions in, 623
- encoder for, 254, **254**, 468–469
- erasure filling decoding in, 259–261
- error correcting coding in, 470, 472–474
- error detecting coding in, separate vs. embedded, 474
- error locators in, 623
- error magnitudes or error values in, 254
- error rate definitions for, 473
- Euclid's algorithm and, 617
- extension of, 467
- feedback shift register and FSR synthesis in, 257–259
- generalized minimum distance decoding in, 261
- generating functions in, 623
- hard decision decoding algorithms for, 475
- hardware vs. firmware implementation of, 470–471
- interleaving vs. noninterleaving in, 472
- large sector size and, 475
- linear coding in, 469
- locator fields in, 253
- magnetic recording systems and, 2249
- magnetic storage and, 1326
- Massey–Berlekamp decoding algorithm for, 257–259, 260, 470, 617, 625–626
- maximum coding and, 254
- maximum distance separable coding and, 254
- modified syndromes for decoding in, 259–260, 469–470
- multiple input/multiple output systems and, 1456
- Newton's identities and, 255, 257, 623, 625
- performance and 472–474
- Peterson's direct solution method for, 255–257, 260, 617
- polynomials and, 254
- power sum symmetric functions in, 623
- primitive elements in, 468
- primitive polynomials in, 468
- primitive vs. nonprimitive types, 253
- redundant array of independent disks and, 474–475
- Reed–Solomon coding for magnetic recording channels and, 467–475
- sequential decoding of convolutional coding and, 2158
- serially concatenated coding and, 2164
- soft bit error rate in, 474
- soft decision decoding algorithms for, 261, 475
- symbol error rate in, 473
- symbol fields in, 253
- syndrome equations for decoding in, 255, 623
- systematic coding in, 469
- t error correcting coding and, 253
- tape drive ECC and, 474
- trellis coding and, 2640
- turbo coding and, 2703
 in underwater acoustic communications, 43
 very high speed DSL and, 2800
- reference signals, in equalizers, 85–86
- reflectarray microstrip/microstrip patch antenna, 1387, **1387**
- reflection, 2065
 cellular communications channels and, 393
 indoor propagation models and, 2013, 2018
 microwave and, 2556–57, **2557**
 parabolic and reflector antenna and, 2082, 2086
 satellite communications and, 196
 ultrawideband radio and, 2759–60
- reflection coefficient, 3, 1401, **1402**
- reflector antenna (see also parabolic and reflector antennas), 169, 179, 180, 184, 187, 1006–17, **1006–16**, 1425–26, **1426**, **1427**, 1425, 2080–88
- refracted near field method, in optical fiber, 435
- refraction, 210–211, **210**
 microwave and, 2558–60, **2559**
 millimeter wave propagation and, 1434–36, **1435**, 1445
- refractive index
 lasers and, 1779
 millimeter wave propagation and, 1434–36, **1435**, 1445
 optical fiber and, 1686, 1715, 1765
 optical modulators and, 1745, **1745**
 solitons and, 1764

- regeneration, 1319, 1759–64
- regenerators, optical fiber, 1707
- region 2 skywave method, 2061–62
- registration, paging, in mobile networks, 1914–28
- regular pulse excitation algorithm, 2824
- regular pulse excitation with long term predictor, 1304, 2356
- relative spectral method, 2378
- relaxed CELP, 2827
- relaxed linear time invariant systems, 689–90
- reliability, 1631–44, 2067
 - asynchronous transfer mode and, 1633–35
 - automatic repeat request and, 1632
 - backup schemes and, 1634–35
 - broadband and, 2655
 - circuit switched networks and, 1632
 - compression and, 631
 - cycle covers and, 1638–39, **1638**
 - cyclic redundancy check in, 1633
 - dynamic restoration in, 1635
 - fail stops in, 1632
 - failure and fault detection/recovery in, 1631–34
 - fault isolation boundaries in, 1632
 - fiber distributed data interface and, 1637
 - free space optics and, 1865
 - high speed/Gigabit LANs and, 1640–42, **1642**
 - intermittent failures and, 1631
 - link and node-based schemes for, 1635
 - link rerouting in, 1633–34, **1634**
 - Menger's theorem and, 1635
 - mesh networks and, 1637–39, **1638, 1639**
 - metropolitan area networks and, 1632
 - minimum spanning tree in, 1639–40
 - models for, 1632
 - multimedia networks and, 1562
 - multiprotocol label switching and, 1640
 - optical fiber and, 439, 1636, **1636**
 - optical modulators and, 1746
 - packet switched networks and, 1632, 1639–40
 - path and link monitoring in, 1633
 - path-based schemes for, 1634–35, **1634**
 - protection of links or nodes in, 1634
 - quality of service and, 1632
 - redundancy and, 1632
 - rings for, 1635–37, **1636**
 - self-healing rings in, 1635, 1637, 1638
 - SONET and, 1634, 1635
 - subnetwork connection protection and, 1635
 - topologies for, 1632–33
 - transmission control protocol and, 1632, 1640
 - transport protocols for optical networks and, 2615–16
 - wide area networks and, 1632
 - wireless multiuser communications systems and, 1605
- reliable protocols, 543
- remote defect indicator, ATM, 207
- remote imaging, in underwater acoustic modem, 20–21, **21**
- remote method invocation, distributed intelligent networks, 725, 727
- remote sensing, parabolic and reflector antenna, 1928
- remotely operated vehicles, acoustic telemetry, 28
- renewal models, in traffic modeling, 1666, 1667
- repeaters, 1504–05, 1999, **1999**
- replica in SPC coding, 1541–42
- reply storms, ad hoc wireless networks, 2888
- reproduction codebook, transform coding, 2596
- reproduction values or points, quantization, 2123
- request to send, 346
- Research and Development in Advanced Communication Technology in Europe, 397
- reservation protocol, 1558
- reservation ALOHA, 130
- reservation-based protocols
 - burst switching networks and, 1801–02
 - flow control, traffic management and, 1655, 1656–57
 - media access control and, 1343, 1347–48, 1552–54
 - mobility portals and, 2195
 - multimedia networks and, 1567
 - optical cross connects/switches and, 1800, **1801**
 - powerline communications and, 2003–04, **2004**
 - satellite communications and, 1232
 - statistical multiplexing and, 2420–32
 - virtual private networks and, 2809
- residential broadband, 2666–73
- residual echo suppressing filter, 1–7, **2**
- residual or multistage vector quantization, 2127
- residual quantization, in speech coding/synthesis, 2345–46
- resilient packet ring, 1637
- resistance
 - antenna, 184
 - loop antenna and, **1295**
 - powerline communications and, 2000
- resistive impedance, in active antenna, 49
- resolution, 1923, 2126
- resolvers, 548
- resonance, 33–34, 48
- resonant frequency/resonant dimension
 - lasers and, 1779
 - microstrip/microstrip patch antenna and, 1359, **1359, 1361, 1361**
- resonant scatter, in free space optics, 1855–57
- resonators
 - microelectromechanical systems and, **1354–55**
 - surface acoustic wave filters and, 2454–57, **2455**
- resource allocation
 - ATM, 552
 - flow control, traffic management and, 1653, 1663, **1663**
 - IP telephony and, 1180
 - multimedia networks and, 1563, 1567
 - packet switched networks and, 1908
 - power control and, 1987
 - radio resource management and, 2088–97, **2089**
 - wireless local loop and, 2951
- resource allocation algorithm, 2090, **2090**
- resource-based admission control, 112, 118
- resource reservation protocol
 - admission control and, 114–115, **115, 116**
 - flow control, traffic management and, 1655, 1656–57, **1657, 1659**
 - IP networks and, 270
 - mobility portals and, 2195
 - multimedia networks and, 1567, 1568
 - statistical multiplexing and, 2420–32
- resource reservation protocol for tunneling, 1596–97
- response time, in satellite onboard processing, 482
- retraining modems, 1498
- retrograde orbits, 1248
- retroreflection, in active antenna, 65
- retroreflectors, in diffraction gratings, 1755
- return loss, parabolic and reflector antenna, 1924
- return to zero
 - optical signal regeneration and, 1759–1763
 - partial response signals and, 1933–34, **1933**
 - wireless infrared communications and, 2927, **2928**
- return to zero DPSK, 1825
- return to zero on off keying, 1827–28, **1827**
- reverberation time, in acoustic echo cancellation, 2
- reverse link, 349–357, **349, 353–355, 355, 362–363, 363, 364, 367**
- reverse shortest path tree, multicasting, 1534
- reversible variable length codes, 2977, **2977**
- RF power amplifiers
 - adjacent channel interference in, 530
 - AM/AM characteristics in, 531, **531**
 - AM/PM characteristics in, 531, **531**
 - amplitude/phase predistorter for, 533, **533**
 - binary phase shift keying in, 531
 - binary PSK and, 530
 - bit error rate in, 530, 535–536, **535, 536**
 - compensation methods for nonlinear distortion in, 532–537
 - direct vs. indirect architecture and learning in, 535
 - inband interference in, 530
 - interference in, 530
 - inverse fast Fourier transform in, 532
 - learning architecture of Volterra-based predistorter in, 535, **535**
 - lookup table for predistortion in, 533–534
 - minimum mean square error predistortion in, 532–533, **532**
 - modulation and, 530
 - nonlinear characteristics of, 531
 - nonlinear distortion in, 530–538, **533**
 - orthogonal frequency division multiplexing and, 530, 531–532, 535
 - peak to average power ratios in, 530, 532
 - phase shift keying and, 530
 - predistorters for, compensating for nonlinear distortion, 530–538, **533**
 - quadrature amplitude modulation and, 530, 532, 535, **536**
 - quadrature phase shift keying and, 530, 531
 - saturation and, 530
 - sensitivity of OFDM systems to nonlinear distortion in, 531–532
 - signal to noise ratio in, 530
 - simulation experiments in nonlinear distortion in, 535–537
 - solid state power amplifiers, 531, 535
 - traveling wave tube amplifier, 531, **532, 535**
 - Volterra-based predistorter for, 533, 534–535, **534**
- rhomboïd antenna, 180
- Riblet linear antenna arrays, 147, **147**
- Rice fading, 785–786
 - cellular communications channels and, 394
 - power control and, 1983
 - satellite communications and, 1226–27, **1226**
 - simulation and, 2291
 - wireless and, 2919
- ridged waveguide transition, 1400, **1400**
- Rimoldi's transmitter, in minimum shift keying, 1467–68, **1468**
- ring cover/node cover, in optical Internet, 2468
- ring linear Golay coding, 890–891
- ring modulator, in amplitude modulation, 139, **139**
- ring topologies
 - backhauling in, 1636, **1636**
 - dense WDM and, 748–757, **749**
 - loopback in, 1636, **1636**
 - matched nodes in, 1637, **1637**
 - optical fiber and, 1716, **1716**
 - reliability and fault tolerance in, 1635–37, **1636**
 - SONET and, 2495–96, **2496**
- ripple carrier signals (RCS), in powerline communications, 1996
- RLC networks and active antenna, 64
- rlogin, 2608
- roaming, 915–916, **916, 1287**
- robust header compression, 2936–37
- robustness, in quantization, 2128
- Rochelle salt transducers (acoustic), 34
- role-based access control, 1649
- rollover effect, in speech coding/synthesis, 2366
- rooftop basis functions, in antenna modeling, 176
- root matching, in antenna arrays, synthesis, 154
- root mean square value, in parabolic and reflector antenna, of surface, 1924
- rotational invariance, in trellis coded modulation, 2632–33
- roughness factors (specular effects), in radiowave propagation, 211–213, **212, 213**
- round trip time
 - flow control and, 1627, 1672
 - transmission control protocol and, 554, 2609, 2612
- rounding (see quantization)
- routers and routing, 541, 547–550
 - ad hoc wireless networks and, 2886–87
 - ATM and, 205
 - Bellman–Ford algorithm in, 2208
 - burst switching networks and, 1802–04
 - constraint based, 1654–55
 - core routers in, 1802, **1804, 1804**
 - Dijkstra algorithm and, 2208
 - distributed intelligent networks and, 719–29, **722, 726**
 - distributed, 1566
 - edge routers in, 1802
 - egress edge router in, 1803, **1803**
 - general packet radio service and, 869–870, **873**
 - global system for mobile and, 914–915, **915**
 - hierarchical, 1566

routers and routing (*continued*)

- ingress edge routers in, 1802, **1803**
- multicasting and, 1531, **1531**, 1533, 1566
- multimedia networks and, 1563, 1566
- multiprotocol label switching and, 1590–1601
- optical Internet and, 2469
- optical multiplexing and demultiplexing and, 1749
- packet switched networks and, 1907, 1909–10, 1913
- satellite communications and, 2115, 2118
- satellite communications and, multihop satellite routing in, 1254
- session initiation protocol and, 2200–01
- shallow water acoustic networks and, 2208, 2211
- source, 1566
- virtual private networks and, 2809
- wavelength division multiplexing and, 2097–2105, 2839–40, **2840**, 2864
- wavelength routing networks in, 1798, 1799–1800
- wireless IP telephony and, 2939, **2939**
- wireless sensor networks and, 2994
- routing and wavelength assignment, 1800, 2845, 2097–2105
 - adaptive routing and, 2102
 - call blocking probability in, 2103
 - constraints on RWA in, 2098–99
 - dynamic routing and wavelength assignment in, 2101–04
 - electrooptic bottlenecks in, 2098
 - embedded topologies in, 2101
 - fairness in, 2103
 - fanout of power splitters in, 2104
 - first fit routing in, 2102
 - fixed-alternate routing and, 2102
 - least loaded routing in, 2102
 - light trees and, 2100
 - light trees in, 2104
 - lightpaths (gamma channels) in, 2098, 2101
 - logical or virtual topologies for, 2100–01
 - maximum reuse routing and, 2102–03
 - minimum reuse routing and, 2103
 - mixed integer linear programming in, 2100, 2101
 - mixed integer programming in, 2100
 - multicast capable OXCs, 2104
 - multicast routing and wavelength assignment in, 2104–05
 - optical cross connects/switches in, 2098–2105, **2099**
 - path mapping in, 2101
 - pathlength and, 2102
 - power splitters in, 2104
 - sparse light splitting in, 2105
 - static routing and wavelength assignment in, 2100–01
 - switching in, 2098
 - topologies for, 2100–01
 - unfairness factor in, 2103
 - wavelength converters in, full, limited, fixed, 2099–2100, **2099**
 - wide area networks and, 2098
- routing control security, 1649
- routing information protocol, 549, 1534
- routing tables, 269, 549
- Rowland circle, diffraction gratings, 1751, **1752**
- RS-232 modems, 1495
- RSA (Rivest–Shamir–Adleman) algorithm, 335, 606, 611, 615, 1152, 1156, 1649
- RS-xxx interfaces, in acoustic modems for underwater communications, 18
- RTP control protocol, 2438
- RTS/CTS flow control modems, 1497
- RTSP, 2198
- rubber duck, 193
- Rudin–Shapiro construction, 893, 1951–52
- run length coding, 1030, 1046
- run length limited, 579–581
 - constrained coding techniques for data storage and, 571–573, **571**
 - magnetic recording systems and, 2248, 2249, 2254
 - magnetic storage and, 1327
 - partial response signals and, 1934
- Runge–Kutta integration, in chaotic systems, 422, 424
- running digital sum, in optical recording, 579
- running time in quantization, 2128
- SAFER+ Bluetooth, 316
- Sagnac interferometers, 1749
- Salutation mobility portals, 2194
- sample matrix inversion, 1886–1903
- sampling, 2106–11
 - analog signal, 2106–11
 - analog to digital conversion and, 2106–11, **2106**
 - antenna arrays and, synthesis, 154
 - bandpass signals and, 2108–2111, **2109**
 - blind equalizers and, 286, 287
 - coding and, 2106
 - community antenna TV and, 522
 - compression and, 631–632
 - cutoff frequency and, 2110
 - frequency for, 2106
 - frequency-domain relationships in, 2107–08, **2108**
 - fundamental range in, 2107
 - holographic memory/optical storage and, 2138
 - image and video coding and, 1026
 - image sampling and reconstruction and, 1079–94, **1081–92**
 - interval for, 2106, **2107**
 - inverse Fourier transform and, 2107
 - lowpass signals and, 2109–10, **2109**
 - Nyquist sampling rate in, 2107
 - photonic analog to digital conversion and, 1960, 1961
 - pulse position modulation and, 2030, 2033
 - quadrature components in, 2109
 - quantization and, 2106, 2122–32
 - quantization error and, 2106
 - simulation and, 2294, **2294**
 - speech coding/synthesis and, 2370, 2340–41
 - theorem of, 2108
 - time-domain relationships in, 2108, **2108**
 - waveform coding and, 2830–32, **2831**, 2837
- sampling frequency, 2106
- sampling interval, 2106, **2107**
- sampling rate, simulation, 2287
- sampling theorem, 2108
- sand and dust attenuation, millimeter wave propagation, 1443
- satellite communications (see also communications)
 - satellite onboard processing; land mobile satellite communications), 208, 876–885, 1223–24, 2179, 2653
 - access points (AP) and, 2117
 - ACES, 196
 - acoustic telemetry in, 22
 - adaptive differential PCM and, 880
 - additive white Gaussian noise and, 1251
 - Advanced Communications Technology Satellite in, 1227, 1228
 - advanced mobile ... service and, 2116
 - ALOHA protocols in, 1232, 1253
 - American Mobile Satellite Corporation in, 2112
 - AMSC, 196
 - antenna arrays and, 141, 169, 189, 196–199, 877–878
 - antenna direction and, 1223, 1228–29
 - apogee and perigee in orbit of, 1248
 - ascending node in orbit of, 1248
 - astra return channel system and, 2120
 - asynchronous DSL and, 2121
 - asynchronous transfer mode and, 2113, 2115, 2120
 - AUSSAT, 196
 - automatic repeat request and, 224–231, 879
 - base station location and, 2117
 - beam patterns for, 877–878
 - Big Leo systems in, 1251
 - binary frequency shift keying in, 1225, **1225**
 - binary phase shift keying in, 1225, **1225**, 1230
 - bit error rate in, 881, 1224, 1225, 1227, 1230, 2120
 - blind multiuser detection and, 298–307
 - block coding in, 1229–30, **1230**
 - broadband and, 2112–13, **2113**, 2115, 2655, 2656, 2664–66, **2665**, **2666**, 2671–73
 - broadcast satellite service in, 877, 1251
 - broadcasting using, 2112
 - C band in, 877, 1251, 2113
 - carrier sense multiple access and, 339–340, **340**
 - cavity backed cross slot antenna in, 197–198
 - cellular telephony and, 2112
 - channel characteristics in, 1224–29
 - circuit switched network architectures and, 1253–54
 - code division multiple access and, 458, 879, 881, 1231–32, **1231**
 - community antenna TV and, 514
 - Comsat and, 876
 - congestion control in, 2120
 - constellation of satellite in, 1247, 1248–50
 - continuous phase modulation in, 1225
 - convolutional coding in, 1229–30, **1230**
 - coverage or footprint in, 1249, 2111
 - crossed drooping dipole antenna in, 197, **197**
 - delay in, 879, 2112
 - demand assignment multiple access and, 879
 - differential phase shift keying in, 1225, **1225**
 - digital subscriber line and, 2121
 - digital voice and television in, 880
 - digital video broadening in, 2112, 2671–73, **2672**
 - directional antenna in, 198
 - diversity techniques in, 1230–31
 - Doppler shift in, 196, 197
 - downlinks in, 1223, **1223**
 - ECHO, 196
 - effective isotropic radiated power in, 881
 - Ellipso, 196
 - error detection and correction in, 1223, 1229–31, **1230**, **1231**
 - ETS-V, 198
 - European mobile satellite and, 2112
 - fading in, 1223, 1226–29, **1226**, **1227**
 - feeder links for, 1251
 - figure of merit in, 1229
 - fixed satellite services in, 877, 1251
 - forward error control in, 878, 1223, 1229–31, **1230**, **1231**
 - forward/reverse path in, 1223, **1223**
 - free space optics and, 1850
 - frequencies for, 877, 1223–24, **1224**, 1251, 2113
 - frequency division multiple access (frequency division multiple access and, 829, 878–881, 1231–32, **1231**
 - frequency shift keying in, 1225

signal to noise ratio in, 1224, 1230
single channel per carrier in, 878
slant range in, 1225–26, **1226**
space communications protocol standards in, 1233
spatial diversity in, 1230–31
split TCP in, 2120
spoofing in, 2120
spot beams in, 877–878, 1249
standards for, 2113
station keeping in, 1248
subscriber links for, 1251
switching in, 2113
target probability in, 2119–20
TCP for transactions in, 2120
TCP/IP and, 2113, 2120
technical issues for implementation of, 2116–19
Teledesic, 196
third-generation wireless systems and, 2115–16, 2115
time division multiple access (time division multiple access and, 878–881, 1231–32, **1231**, 1253
tracking in, 1252
transmission control protocol and, 2120
transmitters for, 878, 2111
transponder for, 878
trellis coded modulation and, 2631
Tundra orbit in, 1250
turbo coding and, 1229–30, **1230**
UMTS terrestrial access radio network and, 2116
universal mobile telecommunication service and, 2116
uplinks/downlinks in, 877, 1223, **1223**, 2115
Van Allen belts and, 2112
very small aperture terminal in, 879–880, 1247
voice over IP and, 2121
Walker delta or rosette constellation in, 1250, **1250**
Walker star or polar constellations in, 1250, **1250**
waveguide and, 1391–92, **1392**
wideband CDMA, 2116
wireless LAN and, 2118
satellite digital audio radio service, 680
satellite diversity, 1231
satellite transport protocol, 1233
Sato algorithm, 92, 291
saturation, in predistortion/compensation in RF power amplifiers, 530
saturation recording, magnetic recording systems, 2248–49, **2249**
scalability
flow control and, 1626
optical filters and, 1732
signal quality monitoring and, 2269
switches, ATM and, 201
wavelength division multiplexing and, 2865
scalar potentials, in loop antenna, 1290–91, 1294
scalar quantization, 2122–32
compression and, 641–642
distortion rate function in, 1213
fixed rate coding and, 2123
Huffman coding and, 2124
image and video coding and, 1035
Lloyd's condition and algorithm in, 2125
transform coding and, 2601–02, **2602**
uniform vs. nonuniform, 2124, **2124**
variable length coding in, 2123
waveform coding and, 2833
scaling mechanisms, in multimedia networks, 1563, 1566
scan blindness (see blindness in microstrip antenna)
scan loss, multibeam phased arrays, 1517
scan mode, Bluetooth, 311–312
scanning
image and video coding and, 1027
microstrip/microstrip patch antenna and arrays, 1375–77, 1384–85, 1387–89
parabolic and reflector antenna and, 2084–86
scanning arrays, 187, 1235–36, 1239–40
scanning diversity, 731
scanning type communications, antenna arrays, 152
scatter
adaptive antenna arrays and, 68–69
cellular communications channels and, 393, 394, 395, **395**
free space optics and, 1851, 1855–57, **1856**, **1857**
indoor propagation models and, 2013, 2018–19
millimeter wave propagation and, 1271, 1434–39, 1445
optical communications systems and, 1491
optical fiber and, 1684–85, **1685**, 1684, 1709, 1710, 1712, 1766, 1843, 1844, 1846
radiowave propagation and, 215
satellite communications and, 196
stimulated Brillouin, 1844, 1846
stimulated Raman, 1843, 1846
tropospheric scatter communication and, 2692–2704
in underwater acoustic communications, 38–40, **39**, 45
wireless transceivers, multi-antenna and, 1579
scatternets, Bluetooth, 315–316
scheduling
flow control, traffic management and, 1654, 1660
multimedia networks and, 1563, 1564–65
packet switched networks and, 1908–09
wavelength division multiplexing and, 656–657
wireless packet data and, 2986–87, **2986**
Schmetterling antenna, in television and FM broadcasting, 2517–36
Schnorr identification protocol, authentication, 614
Schottky photodetectors, 1002, **1002**
Schrodinger equation (nonlinear), in solitons, 1765–66
Schwartz–Yeh approximation, 450–451
scintillations, 1436, 1861–63, **1861**
score and scores vector, maximum likelihood estimation, 1339
scrambling
cdma2000 and, 362
code division multiple access and, 2876, 2877
guided, 579
Hadamard coding and, 934–935
orthogonal frequency division multiplexing and, 1876
synchronous digital hierarchy and, 2499–2500
wideband CDMA and, 2878
scrambling sequences, polyphase sequences, 1975, 1976
Scripps Institution of Oceanography, acoustic telemetry, 24
SDLC, 546
sea clutter, radar, 429–430, **429**
seams in orbits, 1250
seasonal variations in radiowave propagation, 1477, 2063
seawater effects on radiowave propagation, 2064
Seaweb (see also shallow water acoustic networks), 2212–18, **2213**
SECAM standard
high definition TV and, 966–979
terrestrial digital TV and, 2546
second generation wireless systems, 370–371, 377–383, 1479, 1350, 1482–83, 2192
sectored cells, **450**
sectorization, in cochannel interference, 454
sectorization of cells, in wireless multiuser communications systems, 1603
secure hash algorithm, 612
secure MIME, 1651, 2202
secure sockets layer, 1651
security, 1644–52, 1644
access control in, 1153, 1648–51
active attacks in, 1646–47
ad hoc wireless networks and, 2893–95
application level security, 1155
application programming interfaces and, 1651
asynchronous transfer mode and, 1154
audits in, 1650
authentication coding and, 218–224, 1647, 1649
authorization in, 1647
Bluetooth and, 316
bugs and software errors in, 1645
cable modems and, 335
communication security concepts in, 1651
cryptography and encryption (see cryptography)
data confidentiality in, 1648
data integrity and, 1648, 1649
demilitarized zones in, 1650
denial/degradation of service in, 1646, 1647
digital signatures in, 1649
eavesdropping and, 2810
encipherment (see also cryptography), 1648–49
Ethernet, 1646
event detection in, 1650
extranet, 1165–69
firewalls in, 1650–51
general packet radio service and, 875

- syndrome decoder, for cyclic coding, 620
- syndrome equations for decoding, 247–248, 255, 623
- synthesis, in antenna arrays, 153–157, 187
- synthetic aperture radar, 1393, **1393**
- synthetic environment tactical integration visual torpedo program telemetry, 26, **27**
- system capacity, in radio resource management, 2090
- system distance, in acoustic echo cancellation, 6
- systematic (Cartesian) authentication coding, 220, 221
- systematic coding
- cyclic coding and, 619, **619**
 - Reed–Solomon coding for magnetic recording channels and, 469
 - sequential decoding of convolutional coding and, 2141
 - threshold coding and, 2579
- t error correcting coding, 244, 253
- T1 lines, 263
- tabu lists, in quantization, 2130
- tailbiting convolutional coding, 2511–16, **2513**
- a posteriori probability decoders in, 2515
 - applications for, 2516
 - BCJR algorithm for, 2515
 - decoding of, 2515–16
 - Viterbi algorithm for, 2515
- tamed frequency modulation, 584–593
- tank circuits, active antenna, 62
- Tanner graph
- low density parity check coding and, 1311, **1311, 1312**
 - product coding and, 2011, **2011**
- tap leakage algorithm, in adaptive equalizers, 87
- tape drive, for Reed–Solomon coding for magnetic recording channels, ECC, 474
- tapered microstrip transition waveguide, 1400–01, **1400**
- tapering, in leaky wave antenna, 1241, **1242**
- tapped delay line equalizers, 1688–96
- baseband communications systems and, 1690, **1690**
 - decision directed feedback equalizers and, 1693
 - decision feedback equalizers and, 1688–89, 1692
 - feedback filters in, 1690
 - feedforward filters in, 1690
 - filters and, 1690
 - finite length and, 1692–94, **1694**
 - high definition TV and, 1689
 - impulse response and, 1689, **1689**
 - infinite length symbol spaced equalizers for, 1690–92
 - intersymbol interference and, 1688
 - linear equalizers and, 1688, 1691–92
 - matched filters and, 1691
 - minimum mean square error detectors and, 1690, 1691, 1692
 - nonuniformly spaced, 1689–90, **1690**
 - optical synchronous CDMA systems and, 1815, **1815, 1816**
 - performance example of, 1694–95, **1695**
 - quadrature amplitude modulation and, 1690
 - signal to noise ratio in, 1690
 - simulation and, 2289, **2289**
 - sparse multipath channels and, 1688–96
 - tropospheric scatter communications and, 2700–02
 - zero forcing, 1690
- taps, in community antenna TV, 518, **518**
- target lists, for multicasting, 1536
- target probability, in satellite communications, 2119–20
- Taylor distribution (Chebyshev error), 154–157, **155, 157, 187**
- Taylor one-parameter distribution, antenna arrays, 155
- TCP for transactions, 2120
- TCP friendly rate control, congestion control, 1662
- TCP Reno (see also transmission control protocol), 1625, 1630, 1628, 1662
- TCP segments, 541, **544**
- TCP Tahoe (see also transmission control protocol), 1625, 1628, 1662
- TCP Vegas (see also transmission control protocol), 554, 1625, 1628–30, 1662
- TCP/IP, 540–544, 1644
- admission control and, 114
 - ATM and, 264, 273
 - broadband and, 2661–63
 - IP networks and, 267, 268
 - packet switched networks and, 1912
 - radio resource management and, 2094–95
 - satellite communications and, 1232–33, 2113, 2120
 - transmission control protocol and, 2603
 - virtual private networks and, 2807
- TD/CDMA, 2589–90, **2592**
- TDSCDMA
- cell planning in wireless networks and, 369
 - cell planning in wireless networks and, 385–386, 385
- teleconferencing, 540
- Teledesic satellite, 196, 484
- telegraph, 1477
- telemetry (see also acoustic telemetry), 20–22, **21, 37**
- telephone
- acoustic echo cancellation and, 1
 - hands free, 1
 - IP telephony and, 1172–82, **1173**
 - powerline communications vs., 1998
 - transducers (acoustic) and, 29
 - in underwater acoustic communications, 22–23, 36
 - wireless IP, 2931–41
 - wireless local loop standards and systems in, 2947–59, **2948**
- telephony and Internet protocol harmonization over networks, 1181
- telephony routing over IP, 1181
- telescopes, free space optics, 1863–64
- telesonar modems, 2215
- Telesonar telemetry system, 24
- television (TV), 1478
- active antenna and, 50
 - antenna arrays and, 141, 180, 187, 2517–36
 - high definition (see high definition TV)
 - satellite communications and, 880
 - terrestrial digital, 2547–55
 - trellis coded modulation and, ATSC and, 2631–32, **2632**
- Television Allocations Study Organization, 515
- Telnet, 540, 541, 544, 1651, 2608
- temporally ordered routing algorithm, 2211, 2888
- 10Base2, 1283
- 10Base5, 1283
- 10BaseT, 1283, **1283**
- 100BaseT, 1283–84
- TeraNet, 1720
- ternary sequences, 2536–47
- autocorrelation and, 2541–42
 - bounds on sequence correlation in, 2543–44
 - code division multiple access, 2536–47
 - cross correlation in, 2542–43
 - Galois fields in, 2538–47
 - maximal length sequences (m sequences) in, 2540–41
 - phase shift keying and, 2536–47
 - sequence families with low correlation in, 2544–46
 - trace function in, 2539–40
- terrain scatter and diffraction, in millimeter wave propagation, 1445
- terrestrial digital TV, 2547–55
- additive white Gaussian noise, 2547
 - advanced television systems committee and, 2549, 2550

- terrestrial digital TV (*continued*)
- advantages and disadvantages, 2547–48
 - audio coding and, 2552–53
 - bit error rate in, 2547
 - channel coding in, 2548–49
 - digital video broadcasting and, 2549, 2550
 - diversified transmission in, 2554–55
 - indoor reception of, 2554
 - integrated services digital broadcasting and, 2549, 2551–52
 - intersymbol interference and, 2548
 - mobile reception of, 2554
 - modulation in, 2549–50
 - MPEG compression and, 2552–53, **2553**
 - NTSC standard and, 2546
 - orthogonal frequency division multiplexing and, 2549
 - PAL standard and, 2546
 - program and system information protocol in, 2553
 - quadrature amplitude modulation and, 2550–55
 - SECAM standard and, 2546
 - services and coverage for, 2553–55
 - signal to noise ratio, 2547
 - single frequency networks and, 2554–55
 - source coding for, 2552–53
 - standards for, 2546, 2550–52
 - transmission system for, 2548–52, **2549**
 - transport layer and, 2553, **2553**
 - video coding and formats, 2552
- terrestrial microwave communications (see also microwave communications), 2555–72
- test and measurement of optically-based high speed digital communications systems, 2572–79
- TETRA, 379
- text to speech systems, 1304–05, 2380–82
- thermal asperity, in digital magnetic recording channel, 1326
- thermal drift, in optical modulators, 1747
- thermal noise
- adaptive antenna arrays and, 71–72, 74, **74**
 - community antenna TV and, 514–515, 523–524
 - free space optics and, 1858
 - optical fiber systems and, 1843
 - parabolic and reflector antenna and, 1922, 1926–27
 - tropospheric scatter communications and, 2697, 2698
- thermocapillary switches, 1792–93, **1792**
- thermoelectric element lasers, 1781
- thermooptic planar lightwave circuits, 1703–04
- thermooptic switches, 1785
- Thevenin equivalent circuits, antenna, 184, **185**
- thin film filters (see also dielectric thin film stack interference filters), 1723, 2446
- thinned arrays, 162–163
- thinnet/cheapernet, 1283
- thin-wire theory for antenna, 175
- third-generation wireless, 125–126, 371, 385–391, 1479, 1483, **1483**
- microelectromechanical systems and, 1350
 - satellite communications and, 2115–16
 - session initiation protocol and, 2198
- Third Generation Partnership Project, 126, 358, 397, 918, 1316, 2932
- third order dispersion, solitons, 1766–67
- third party call control, in session initiation protocol, 2198
- threading, protocols, in MAC, 1348
- 3D antenna array, 151–152, **152**
- 3G.324 standard, 2980
- threshold coding/ decoding, 2579–85
- a posteriori probability (APP) algorithm and, 2580, 2584
 - block coding and, 2583–84
 - convolutional coding and, 2581–83, **2582**
 - convolutional self-orthogonal coding and, 2582–83, 2584
 - generator matrix in, 2579
 - Hamming coding and, 2579–80
 - history and development of, 2580
 - L step orthogonalization in, 2580
 - parity checks and, 2580–81
 - systematic encoding in, 2579
- threshold current, in lasers, 1778
- threshold effect, 820–821
- threshold sampling in waveform coding, 2837
- thresholds, in speech coding/synthesis, 2364, **2364**
- throughput
- ALOHA protocols and, 342
 - automatic repeat request and, 226, 228–230
 - broadband and, 2655
 - cell planning in wireless networks and, 385, **385**, **386**
 - frequency division multiple access (frequency division multiple access and, 827, **827**
 - media access control and, 1344
 - packet rate adaptive mobile receivers and, 1902–03, **1902**
 - transmission control protocol and, 554
 - wireless packet data and, 2984–85
- throughput per slot rate, ALOHA protocol, 128
- Thuraya satellite onboard processing, 484
- time congestion, in traffic engineering, 491, **491**
- time constrained ALOHA, 131
- time delay, 1436, 1937
- time deterministic time/wavelength division multiple access, 1555
- time difference of arrival, 2690, 2963
- time diversity, 276, 371, 1481
- time division CDMA, 123
- time division coded modulation, unequal error protection coding, 2763–69, **2764**, 2763
- time division duplex
- adaptive receivers for spread-spectrum system and, 96
 - admission control and, 123
 - Bluetooth and, 310
 - cell planning in wireless networks and, 385–386
- time division multiple access (time division multiple access, 458, 825, 2274, 2585–92
- acoustic telemetry in, 25
 - adaptive receivers for spread-spectrum system and, 95–96, **96**
 - admission control and, 120, 123
 - advanced mobile phone service and, 2586
 - antenna arrays and, 163
 - ATM and, 2907–09
 - automatic repeat request and, 225
 - Bluetooth and, 309–310
 - broadband wireless access and, 318, 320
 - burst types for, 2588, **2588**
 - cable modems and, 324, 334–335
 - carrier sense multiple access and, 340–341, **340**
 - cdma2000 and, 358
 - cell planning in wireless networks and, 377, 380
 - cellular telephony and, 1479
 - channel/in channel modeling, estimation, tracking, 409–410
 - chirp modulation and, 445, 446
 - cochannel interference and, 448, 453–454, **453**, 455
 - code division multiple access and, 2586, 2590
 - community antenna TV and, 523
 - enhanced data rate for GSM evolution and, 2589
 - frequency division multiple access (frequency division multiple access and, 828, 829, 2586
 - general packet radio service and, 2589
 - global system for mobile and, 911–912, **911**, 2589
 - hybrid systems using, 2586, **2588**
 - IMT2000 and, 1095–1108
 - intelligent transportation systems and, 503, 504–505
 - interference and, 1130–41
 - local multipoint distribution service and, 318, 320
 - media access control and, 1343–1347
 - mobile radio communications and, 1481–82, **1482**
 - Nordic Telecommunications and, 2586
 - optical fiber and, 1808
 - orthogonal transmultiplexers and, 1880–85
 - packet rate adaptive mobile receivers and, 1886
 - physical layer subscriber signals in, 2586–89
 - polyphase sequences and, 1975–76
 - powerline communications and, 2003
 - principles of, 2586
 - radio resource management and, 2090, 2091–93
 - satellite communications and, 878–881, 1231–32, **1231**, 1253
 - satellite onboard processing and, 477, 479
- shallow water acoustic networks and, 2208, 2212, 2215
- signal and system structure in, 2586–89, **2587**
- software radio and, 2312, **2312**, 2314
- spatiotemporal signal processing and, 2336
- system structure for, 2589, **2589**
- TD/CDMA and, 2589–90
- turbo product coding and, 2727–37
- underw/in underwater acoustic communications, 44
- wireless local loop and, 2950–51, 2955
- wireless multiuser communications systems and, 1602, 1609
- time division multiplex, 1906
- ALOHA protocol and, 130
 - Bluetooth and, 315
 - broadband wireless access and, 318, 320
 - Ethernet and, 1512
 - flow control and, 1625
 - H.324 standard and, 920–922, **921**
 - local multipoint distribution service and, 318, 320
 - medium access control and, 1552, 1553
 - multibeam phased arrays and, 1514
 - optical cross connects/switches and, 1799
 - optical modulators and, 1741
 - tropospheric scatter communications and, 2693
 - wavelength division multiplexing and, 2864
 - weighted, 1552
- time division WDMA, 1553
- time domain, in antenna modeling, 169
- time domain constraints, in optical recording, 579
- time invariant digital filters, 687, 700
- time of arrival, in wireless systems, 2690
- time representation (TSR) sequence, 288
- time reversal space time block coding, 2329, 2330
- time slot assignment, in ADSL, 1574, 1575
- time slots, 1625, 1667
- time spread multiple access, 1348
- time stretching using dispersive optical elements, 1968, **1968**
- time to live field, MPLS, 1594–95
- time variance in radio channels, 393, 394–395
- time varying coding, 581
- time varying maximum transition run length coding, 1332
- timeouts and retransmission, in TCP, 2611–12
- timescale, 1667, 1908
- timing and synchronization, 2478–79
- timing errors, orthogonal frequency division multiplexing, 1875–76
- timing jitter, 1759, 1767
- timing window, in constrained coding techniques for data storage, 573
- tinygrams, 2609
- TM multicasting algorithm, 1533
- Toeplitz symmetric matrix, in linear predictive coding, 1263
- token bus, 547
- token ring, 345, 547, 549, 1345–46, 1529
- tonpiz sonar transducer, 35, **35**
- top down processing, in
- speech coding/synthesis and, 2363
- topologies
- ad hoc wireless networks and, 2886
 - Ethernet and, 1505, **1505**
 - fault tolerance and, 1632–33
 - free space optics and, 1851
 - optical fiber and, 1715–17
 - powerline communications and, 1999–2000, **1999**
 - reliability and, 1632–33
 - routing and wavelength assignment in WDM and, 2100–01
 - shallow water acoustic networks and, 2208
 - wavelength division multiplexing and, 651
 - wireless communications, wireless LAN and, 1285, **1285**
- trace function, in feedback shift registers (FSR), 796
- track density, in hard disk drives, 1321
- tracking
- channels (see channel tracking in wireless systems)
 - satellite communications and, 1252
 - ultrawideband radio and, 2761

- tracking and data relay satellite, 1519
- tracks, in storage media, 1320–21, 2248
- traffic activity factors, 1608
- traffic analysis attack, 1646
- traffic channels, in IS95 cellular telephone standard, 349
- traffic computation, in cell planning in wireless networks, 380

 - transmission control protocol and, 2984, 2989
 - visitor location register in, 2987
 - wireless LANs and, 2982
- wireless PAN (see also personal area networks), 502, 508, 2682
- wireless routing protocol, ad hoc wireless networks and, 2886, 2888
- wireless sensor networks, 2990–96
- wireless session protocol, 2902
- wireless systems (see also Bluetooth; land mobile satellite communications; mobile radio communications), 208, 308, **408**, 1223–34
 - ad hoc networks in, 2883–99
 - adaptive receivers for spread-spectrum system and, 96–97
 - admission control in (see admission control in wireless networks)
 - analysis techniques for, 2919–24
 - angle of arrival in, 2689–90, **2689**
 - antennas for (see also antennas for mobile communications), 169, 179–180, 184, 188–200
 - asynchronous transfer mode and, 2906–15, **2907**
 - bit error rate, 2923, **2924**
 - bit interleaved coded modulation and, 276
 - blind equalizers and, 296–297
 - Bluetooth and, 307–317
 - broadband access (see broadband wireless access)
 - burst switched networks and, 122
 - carrier sense multiple access and, 346
 - carrier to interference ratio in, 121, 379, **379**
 - cdma2000 and, 385–386
 - cell planning in, 369–393
 - cells in, 369–393
 - in channel modeling, estimation, tracking, 398–408
 - channel assignment problem and, 382–383, **383**
 - channel borrowing and, 125, **125**
 - channel tracking in (see channel tracking in wireless systems)
 - circuit switched networks and, 122, 371
 - coding division multiple access and, 372
 - common packet channel switching and, 123
 - compression of data and, 371
 - coverage area and, 372
 - data services on, 371
 - design of, 2915–25
 - diversity reception in, 2919–20
 - Doppler effect, Doppler spreading in, 2916–18., **2917**, **2918**
 - equal gain combining in, 2920, 2921–22
 - Erlang B blocking in, 379–380, **379**, **380**
 - extremely low frequency in, 758–780
 - fading in, 2915, 2916–18
 - first-generation systems in, 370
 - fourth generation systems in, 371–372, 391–392
 - free space optics in (see free space optics)
 - frequencies for, 208
 - frequency assignment problem and, 382–383
 - frequency division duplex and, 385–386
 - geolocation of, indoor, 2688–90, **2689**
 - global system for mobile and, 369–372, 377–383
 - global vs. local parameters for, 372
 - grade of service and, 379–380
 - guard channels and, 124, **124**
 - H.324 standard for, 918–929, **919**
 - history of, 369–372
 - home area network and, 2685–88, **2687**
 - home networking and, 2684–88, **2685**
 - IMT2000 and, **386**, 392, 1094–1108
 - indoor propagation models for, 2012–21
 - interference and, 121, 377–380, 1151–30
 - Internet and, 371
 - IP networks and, 392
 - local multipoint distribution services in, 1268–79
 - location in, 2959–72
 - lossy compression and, 371
 - low density parity check coding and, 1316
 - maximal ratio combining in, 2920
 - media access control and, 1342–1349
 - microelectromechanical systems for, 1349–1356
 - mobility portals and services for, 2190–96
 - modulation and, 371
 - Monte Carlo simulation and, 2916
 - multibeam phased arrays and, 1513–21, **14**
 - multimedia service in, 371
 - multipath and, 2916–18
 - multiple antenna transceivers for (see also multiple antenna transceivers), 1579–90, **1580**
 - multiple input/multiple output systems and, 1450–56, **1450**
 - multiuser systems (see multiuser wireless communication systems)
 - noise and, 2915
 - nonlinear least square in, 2690
 - optimization in, 372
 - orthogonal frequency division multiplexing and, 2916
 - outage probability in, 2922
 - packet switched networks and, 122, 371
 - paging and registration in, 1914–28
 - parabolic and reflector antennas and, 2080
 - planning for, 372
 - power control and, 121–122
 - quality of service and, 372, 379, **379**, 1450, 2915
 - queuing priority and, 124–125, **125**
 - radio resource management and, 2088–97, **2089**
 - received signal phase in, 2690
 - received signal strength in, 2690
 - satellite communications and, 2111–22
 - second generation systems in, 370–371, 377–383
 - security and, 1155–56, 1646
 - selection combining in, 2920–21
 - shadowing and, 2922
 - Shannon or channel limit in, 2915
 - signal correlation in, 2917–18
 - signal to interference ratio in, 121
 - signal to noise ratio, 121–122, 2915, 2919, 2921
 - space-time coding for, 2324–32, **2324**
 - spatiotemporal signal processing in, 2333–40, **2333**
 - standards for, 371
 - system model for, 2922–23, **2923**
 - TDSCDMA and, 385–386
 - third-generation, 125–126
 - third-generation systems in, 371, 385–391
 - time difference of arrival in, 2690
 - time division duplex and, 385–386
 - time division multiple access and, 377, 380
 - time of arrival in, 2690
 - traffic computation for, 380
 - trellis coded modulation and, 2922
 - trellis coded PSK, 2922
 - Universal Mobile Telecommunications Systems and, 371–372, 385–391
 - voice services on, 371
 - wideband CDMA and, 372, 386
 - wireless application protocol and, 2899–2906
 - WRC2000 and, 392
 - wireless telephony application, 2901
 - wireless transaction protocol, 2902
 - wireless transmission control protocol, 1233
 - wireless transport layer security, 1156, 2902
 - wiretapping, 1646
 - Woods Hole Oceanographic Institute, acoustic telemetry in, 24
 - Woodward–Lawson method, 158–159, **159**, 187
 - World Administrative Radio Conference, 1478
 - world wide web (see also Internet), 271–274, 540
 - World Wide Web Consortium, 2193, 2899
 - worst case fair weighted fair queuing, 1660
 - WRC2000, 392
 - write once read many devices, 1319, 1737
 - write process
 - CDROM and, 1734
 - digital magnetic recording channel and, 1323–1324
 - digital versatile disc and, 1738
 - hard disk drives and, 1320
 - magnetic recording systems and, 2249
 - magnetic storage and, 1320, 1326
 - optical memories and, 1733
 - X.25, 546
 - X.509, 1649
 - X2 protocol, 1498, 1499
 - Xerox PARC and local area networks and, 1279
 - Xon/Xoff modems and, 1496, 1497
 - XORing cryptography and, 608–609
 - Xpress transport protocol and, 2616, 2617, 2620
 - Yagi–Uda, antenna arrays and, 161, **161**, 169, 187
 - Ymodem, 1497
 - Z transforms, digital filters and, 690–691
 - zenith angle, 2067
 - zero crossing rate, speech coding/synthesis and, 2371
 - zero force projection, wireless transceivers, multi-antenna and, 1588
 - zero forcing
 - equalizers and, 81, 82–83, 88
 - tapped delay line equalizers and, 1690
 - multiple input/multiple output systems and, 1455
 - zero input response, 2347
 - zero knowledge, authentication and, 614
 - zero state response, 2347
 - zero tree coding, 1046–47
 - zigzag scanning, image and video coding and, 1046
 - Zmodem, 1497
 - zonal sampling in waveform coding and, 2837
 - zone-based hierarchical link state, 2890
 - zone bit recording, 1321
 - zone of authority, 548
 - zone routing protocol, 2889
 - zoned linear velocity, 1735
